SCIENCE AND MANUFACTURES

THE occurrence in one week of meetings held by the Iron and Steel Institute, and by the Institution of Mechanical Engineers, seems to offer a fitting occasion for further remarks on the connection between science and art, between practical construction and theoretical investigation. A few months ago, in an article on the same subject, it was pointed out how these two branches of knowledge were found to work in harmony for the ends of each—science instructing art, art supporting and ministering to science; and this truth was illustrated by a variety of examples. Others which have occurred since that time may be touched upon before we conclude. At this moment we are anxious to insist once more on the need which exists to draw this union between art and science closer than it has ever been drawn before, and to remove all obstacles which may stand in the way of its fullest realisation.

The necessity for this union lies in the fact that England has an industrial supremacy to maintain, and that year by year its maintenance becomes more difficult in the face of keen and jealous competition. Whatever may be said in Parliament, all practical men are aware that the great tide of prosperity, promised last year by the President of the Board of Trade, has not yet begun to flow; that on the contrary there was never perhaps a time when the special industries of England were more depressed, or their outlook more gloomy. The fact that the steel-rail makers of England have banded themselves with those of France and Belgium into an association for the maintenance of remunerative prices speaks volumes, not only as to the severity of competition, but as to the sources from which that competition comes. On the other side we see the iron-masters of America extending their output year by year, and her manufacturers entering into competition with us in neutral markets, while jealously excluding us from their own.

What is to be the remedy for this state of things? How is the demand for manufactured articles, and for the raw materials out of which those articles are made, to be once more equalised with the supply? Unless some vast market, such as China or Central Africa, can be opened up to European commerce, the only chance seems to lie in a new departure; in some great cheapening of production, or cheapening of transport, comparable to that which was effected by the development of railways. Now what is the physical fact lying at the basis of railway locomotion? It is simply this, that iron laid in the form of a track offers a resistance to rolling which, as compared with an ordinary road, is insignificant, whilst at the same time it offers a resistance to sliding large enough to utilise to the full the vast tractive power of the modern locomotive. The first point had long been known; the second was seized by the practical genius of George Stephenson, and enabled him at once to solve the problem of high speed locomotion. In so doing he owed nothing to science; but science might have discovered the fact, and would have done so with small trouble, if the idea had been put into her head—if, in fact, there had been in England that union of theory with practice which it is our present aim to advocate.

What is wanted now is that science shall point out some other fact of nature, new or old, which practice may seize upon, turn to her own ends, and make the basis of some new industrial development. It is easy to indicate various directions which such a development might take. Thus there is great need of some system of light railways which can be laid down on ordinary roads, and so cheaply that the traffic available on such roads may be sufficient to pay a fair return on the capital. It is impossible to calculate the advantages which would spring from the wide extension of such "third-class railways," as they are called in Germany. Again, the storage of power, such as that of the tidal wave, with cheap and ready means for giving it out when and where it is needed, offers a wide field for invention, and may lead to the most fruitful results. The transmission of power to long distances, whether by electricity, compressed air, or otherwise, is a somewhat similar problem, which at present occupies the attention of many engineers and men of science. Lastly, the more homely subject of house-building offers at this

moment special inducements to constructive genius. If houses could be built, by the use of iron or otherwise, at, say, half their present cost, the problem of sheltering our poor would be solved; unsafe and ruinous tenements would disappear, and a demand would set in for building materials and labour such as the world has never known.

Here, however, the question arises, Supposing that science and art should combine successfully for any such purpose, is it in England that the development will take shape?

At the time of the last industrial epoch, that of the introduction of railways, it would have been safe to prophesy that this would be the case. It is by no means so certain now. As regards cheap transport, for instance, the most promising recent invention in this field, viz. the caustic soda condenser previously described by us, was brought out in Germany. Other improvements in the same field, such as the portable railways of De Cauville, the rack railway of Riggenbach, the cable tramway of Hallidie, the fireless engine of Francq, the iron sleepers which are rapidly becoming universal in Germany, have all taken their rise either on the Continent or in America. The storage of power, in its only practical form, that of the secondary battery, owes its origin to Planté and Faure. The transmission of power is being worked out by Siemens in Berlin, and by Deprez and Tresca in Paris. Lastly, as to building, no one can travel abroad without seeing that as regards scientific architecture, England stands far nearer the bottom than the top in the scale of civilised nations.

What is the reason of this? Why is England thus lagging behind in the race? The answer is not far to seek. In America, in France, above all in Germany, the union between science and art is far more close and cordial than with us. Every practical constructor or manufacturer is anxious to know all he can of science, every scientific professor desires to mix practice with his theory. Thus on the one hand we find ordinary engineers drawing on all the resources of mathematics for the solution of such problems as the proper section of rails or the resistance of trains; on the other hand we see Clausius, perhaps the greatest of German physicists, devoting two long papers to investigate the working theory of the dynamo machine. But a concrete instance will make our meaning clearer. Within the last few days we have inspected a safety lamp, of which some thousands have already been sold for the German mines. It has many points of excellence, but we need only dwell upon one. It is well known to be most important that a miner's lamp should be locked in such a way that he cannot, if he will, open it; and it has been found very difficult to provide any simple kind of lock which it is beyond the resources of a clever workman to tamper with. In this lamp the difficulty is got over by making the upper part screw into the lower, while inside the lamp there is a catch or pawl, which, as in a common ratchet, prevents the screw from being turned the opposite way. Hence, that the lamp may be unscrewed, the pawl must be drawn out of place. In the overseer's office this can be accomplished by means of a powerful horse-shoe magnet. The pawl has a tail, which is attracted by the magnet when the latter is placed in contact with the side of the lamp. The tail moving towards the magnet, the pawl moves in the opposite direction, and so allows the upper part of the lamp to be unscrewed, while the lower is held as if in a vice by the same magnetic power.

Now here we have a simple and beautiful contrivance for effecting an important practical object. It is merely the application of a well-known scientific principle to solve a special problem in construction; but it never could have been invented except by one to whom the resources of science and the needs of art were equally familiar—who was at once a physicist and an engineer. Now it cannot be questioned that in England we can boast many of the highest authorities in science, many men of the highest skill in practical construction; but the union of the two is comparatively rare, and yet it is this very union—the application of the scientific spirit to the things of common life, as so well illustrated in the excellent paper by Prof. Newcomb, published elsewhere—which is the vital necessity of the age.

The fault is not all on one side. Science sometimes looks down on Practice as a rough, prosperous mechanic, interested in nothing but his work and his wages, while Practice sneers at Science as a fine gentleman, too much absorbed in crotchets to be worth any attention or respect, and who, if he had not some one to look after him, would shortly be in the workhouse.

As an instance we may take the magnetic balance lately described by Prof. Hughes. This beautiful instrument promises at least to supply a want long felt by the makers and users of iron—the want of some method of "mechanical analysis"—some means of determining the physical and chemical properties of a given material—without testing it to destruction, as is now unavoidable. But whilst thus appealing on the one hand to manufacturers, the invention appealed on the other hand to electricians, as offering a ready index of the magnetic qualities of a metal. By the latter it has been welcomed, and is being used, as, for instance, by Mr. Preece, for the testing of telegraph-wire; but, so far as we know, not a single manufacturer or engineer has thought it worth while to encounter the small amount of trouble and expense which would be needed to test thoroughly the capabilities of the instrument in determining the mechanical properties of finished iron or steel.

We by no means wish to imply that no progress is being made in the direction here pointed out. The work undertaken by the City and Guilds Institute, the foundation of scientific colleges, such as those at Birmingham, Sheffield, Leeds, Nottingham, and elsewhere, the appointment of a Committee on Technical Education, the delivery of scientific lectures at the Institution of Civil Engineers—these are all signs that the gap existing between art and science is at last recognised, and that endeavours are being made to draw them together. Moreover, the old "rule-of-thumb" engineer is rapidly passing away, and a new generation is springing up, who, if they do not possess much science themselves, are at least alive to its value. The testing machine, for instance, is becoming a recognised institution in large workshops, where not many years ago it would have been scouted as absurd. In the skilful hands of a practical engineer, Mr. Wicksteed of Leeds, it has been made to record its own variations of stress by a self-drawn diagram, and this record seems likely to throw fresh and unexpected light on the physical

problems of extension and rupture. The same gentleman has both discovered and applied a new and most remarkable phenomenon in friction; the fact, namely, that if we give a rotary motion to a body which is in contact with another, not only is the friction diminished in the direction of motion, but the friction in the perpendicular direction is also diminished, apparently in at least an equal degree. Hence, for instance, by rotating the leather packing of an hydraulic ram, it becomes quite free to move in its cylinder in obedience to a difference in pressure on one side or the other. Here we have, once more, science helping art, and art in return throwing light upon the path of science.

These facts, and others like them, are encouraging signs, but we must repeat that something more than signs is needed. The work must be not only begun but finished, the bonds of union must be drawn close, and that quickly, or England will find that it is too late, and that she is once more ready to do the work of the world just when the world has left her no work to do.

FORSTER'S "STRATA OF THE NORTH OF ENGLAND"

A Treatise on a Section of the Strata from Newcastle to Cross Fell. By Westgarth Forster. Third Edition, revised and corrected to the present time by the Rev. W. Nall, M.A., with Memoir. 8vo. (Newcastle-upon-Tyne, 1883.)

THE position of Forster's "Strata" among the classics of geological literature in England is so well defined that a reissue would be welcome to many readers, as although the progress both of coal and metal mining during the long interval that has elapsed since the appearance of the last edition in 1821 has done much to supplement, and in some instances modify, the author's evidence, it must ever remain as a splendid monument of geological investigation as carried on in the earlier years of the century. Unfortunately, in the present issue the editor has carried out his duties in a very thorough-going fashion; to use his own words, "Some alterations have been made in this edition of the 'Strata.' Parts I. and II. have been revised and rearranged; Part III. has been partially recast; some of the old sections have been extended, and other sections have been given; obsolete matter has been expunged, and new matter in the form of notes has been added."

If the editing had been confined to the last-mentioned additions, or rather if all the alterations had been supplied as footnotes or in the form of appendixes, such a course would have been perfectly justifiable, and the value of the text would have been enhanced; but from the course adopted of shifting the original text backwards and forwards to bring it into harmony with more modern views, and rearranging the sections even to the extent of renumbering the beds of limestone in the lead-measures, and the intercalation of new subdivisions in the limestone series not contained in the original, the work has become so strangely metamorphosed that any one taking it for what it professes to be, namely, Westgarth Forster's "Strata," will be liable to be strangely misled, unless he carefully compares it with the original text. This is much to be regretted, as the editor's work has evidently been a labour of love, and it is strange that he should have so ill-used his favourite volume.

The editor has, however, done one good service deserving grateful mention by supplying a memoir of the author, which is, however, eccentrically interpolated between the original table of contents and the text. From this we gather many interesting particulars of the life of one who may be regarded as the prototype of the Sopwiths, Bewicks, and other mining engineers in the north of England, who have become famous not only in their original districts, but in all parts of Europe and America. It is somewhat surprising to learn how in the year 1807 the material for the first edition of the "Strata" was collected by Forster, who for that purpose resigned the agency of the Allendale lead mines. The volume was issued in 1809 in the same year with William Smith's first geological map of England, and at once became exceedingly popular; and thenceforward the author was recognised as one of the leading men in his profession, and was fully engaged in many surveys until his retirement in 1833. During this active period of twenty-three years he worked in nearly all the mineral districts of England and Wales, with the exception of Cornwall and Devon, and also visited Spain and North America. The American trip was made in 1831, in pre-steamboat days, in the fine packet-ship *Napoleon*, making a fairly good voyage of thirty-two days across the Atlantic. The districts visited were Pottsville and Mauch Chunk, in the anthracite district of Pennsylvania, which had then been discovered only eight years, and the Phœnix Copper Mines in Connecticut.

The later years of his life were clouded by misfortunes due to losses in working some lead mines in Wales, and before the spring of 1829 he had spent nearly all that he possessed in abortive trials, at a period of extreme depression in the lead trade. In 1833-34 failing health led him to retire from active work, and on November 9, 1835, he died at Garrigill, in Cumberland, in his sixty-third year. In the author's words, Forster rendered valuable service to the sciences of mining and geology, and for that service, if for no other reason, his name will continue to be remembered for a long time to come. H. B.

OUR BOOK SHELF

A Manual of Chemistry. By Henry Watts, B.A. (London: Churchill, 1883.)

THIS work is stated by the author to be intended for a student commencing the study of chemistry, and, as he states in his preface, this volume commences with a short sketch of the more important elementary bodies, the principal laws of chemical combination, and the representation of the constitution and reaction of bodies by symbolic notation. In addition to this there is a large section on chemical physics, including the mechanical properties of gases and the chief phenomena of heat, light, magnetism, &c. For an elementary work, as intended by the author, it is somewhat dense, and would be certainly apt to frighten a beginner in chemistry. The sections on physics alone, comprising Part I., occupy very nearly 150 pages, and within this narrow space we find that in the domain of light we have refraction, reflection, circular polarisation, &c., treated at considerable length. In magnetism and electricity we have a very complete and exceedingly condensed mass of information, certainly much too complete and condensed for an elementary text-book. In the purely chemical section, forming Part II., the work is extended so as to include a considerable chapter on crystals and the more recent extensions of the atomic theory, and also to the so-called rare metals,

which we find treated at considerable length. As to the arrangement of the chemical part, the method adopted in "Miller's Chemistry" of arranging the elements under the terms metals of the alkaline earths, &c., has been adopted, which is a very excellent method of arrangement for teaching purposes, as it allows of elements with similar properties being compared. There is evidently throughout the whole of the book a tendency to condense far too much into a small space. It would be an exceedingly difficult book indeed to be put before an *absolute* beginner. The explanatory part is reduced apparently as much as possible, although a great many facts are crammed in, certainly in good order; but still a beginner requires very much more explanation of facts than is to be found in this book. On that account, and being more an epitome of facts than explanations, especially in the chemical portion, it is scarcely possible to criticise it. The arrangement is very excellent and the details are well up to date. We notice that ozone has been put in in the form of an addendum: surely its position is closely in connection with oxygen. It is very liable in this position to be overlooked, or at any rate neglected, by a student. As there is such a considerable amount of attention given to the rare metals, especially vanadium, many of its compounds being detailed, it is somewhat surprising that davyum, though perhaps not yet absolutely settled, is not mentioned along with them. On looking carefully through the book, a number of points occur in which more explanation, or even an explanation of formulæ, would be very advantageous; but on the whole Mr. Watts is to be complimented on having produced a very complete, though certainly not quite elementary, manual on the science.

Arithmetical Chemistry. By C. J. Woodward, Birmingham and Midland Institute. (London: Simpkin, Marshall, and Co., 1884.)

THIS is almost a book of questions selected from the Cambridge and Oxford Local, University of London, Science and Art Department, and other examination papers. It is divided into headings on laboratory calculations, where, after an example of a volumetric or gravimetric analysis, a number of exercises and questions follows, and gas analysis with corrections of gases for pressure, &c., and determinations of vapour densities, specific and atomic volume, specific heat, calorific power, calorific intensity, kinetic theory of gases, and diffusion. The explanations are in most cases short and to the point, but the immense number of examples and exercises given tend to make it a "getting-up" book for examinations rather than a book to work with in the laboratory.

Experimental Chemistry. By J. Emerson Reynolds. Part III. (London: Longmans, Green, and Co., 1884.)

PROF. REYNOLDS, in the first and second parts of this little work, has departed somewhat from the usual method adopted in chemical books for junior students. The first and second parts deal entirely with the non-metals and their compounds, acids, &c.; while the third part is devoted to metals. It is divided into numbered experiments for the student to perform in rotation, and should be exceedingly valuable to medical and other students who have only a short time at disposal for practical chemistry. There is no attempt at systematic analysis, but the experiments are sufficiently logically arranged to enable a student who gives his attention to them to be able to perform any simple qualitative analysis. At the same time each experiment is very fully explained, and the reactions expressed in most cases with equations. Part III. is supplemented by a series of analytical tables at the end, which, however, are not very clear. They are certainly somewhat too complex for the class of student for which the book is intended. On the whole, however, it is a very excellent work.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

Reply to Mr. Grubb's Criticisms on the Equatorial Coudé of the Paris Observatory

I HAVE just received the last number of the *Scientific Transactions of the Royal Society of Dublin*, containing a description of an instrument analogous to the equatorial constructed on a principle which I published in 1871 in the *Comptes Rendus*. Since it seems to me indispensable after I have studied Mr. Grubb's memoir to reply to it publicly, I beg you to insert this note in NATURE. In order to give greater importance to the modifications imagined by himself, the author, Mr. Grubb, submits the instrument imagined by me to a very severe criticism, and attributes very severe defects to it. There is no doubt that there is a considerable difference between the instruments in question. One of them, in fact, as experiments carried on during two years have proved, lends itself to the execution of all possible astronomical researches under the best possible conditions for securing precision, while the other, according to the description given in the publication above cited, renders impossible a very great part of the researches to which an equatorial is specially destined. Further on I shall insist on this difference, but I wish first of all to reply to Mr. Grubb's objections and to show that they are in all points contrary to the fact.

To give weight to his argument Mr. Grubb examines a case of the construction of an instrument of 27 inches aperture, and he anticipates in the construction the following difficulties, which he considers insurmountable:—(1) The optical difficulty of constructing a large plane mirror. (2) The practical difficulty of procuring a disk of the necessary dimensions. Mr. Grubb affirms that there is no glass-works capable of making a disk of glass so large. (3) The difficulty of moving a mirror of which the weight, according to Mr. Grubb's calculations, will be very nearly half a ton. (4) The dearness of the instrument, which would cost more than an ordinary equatorial, plus dome and observatory.

I will discuss these points one by one. (1) The construction of plane mirrors is a settled question nowadays. Many astronomers have been able to convince themselves that in the equatorial coudé of 11 inches aperture the introduction of a plane mirror of 16 inches in no way marred the definition. The brothers Henry, who constructed this mirror, have just made another of 40 inches diameter, which leaves absolutely nothing to be desired in this respect. This difficulty, moreover, is so little felt or feared by our opticians that the price of a similar mirror for an instrument coudé is only about a quarter of the price of an object-glass, in spite of the great difference of their respective surfaces. Thus, for an object-glass of 27 inches, the price of which is 70,000 francs, that of a plane mirror of 38 inches is 18,000 francs. For an object-glass of 40 inches, price 200,000 francs, the corresponding mirror of 58 inches only costs 40,000 francs. I admit, nevertheless, that in this respect Mr. Grubb may have had apprehensions. In the past, in fact, serious difficulties have been met with in the production of plane mirrors, but my own personal experience has enabled me to realise the real cause of this want of success. Up to the present time, to satisfy preconceived ideas it was believed that to establish rapidly an equilibrium of temperature it was necessary that the thickness of the mirror should be small. Then, under the influence of a tightening, however slight, or only a flexion, the mirrors were deformed unequally, and consequently produced an obvious alteration in the beauty of the images. The brothers Henry, studying the same question by different processes, have arrived at the same conclusions. In giving to the disk a sufficient thickness, the production of a plane surface is not more difficult than any optical surface whatever. The means of verification are so delicate that in a mirror of 40 inches diameter an error of 1/50,000 of a millimetre can easily be determined and eliminated. So if there be a sphericity in the mirror, the radius of curvature will have at least 1600 leagues, that is to say, about

the radius of curvature of a bath of mercury, and in taking still greater pains it will be possible to go further and to reach an exactitude such that the radius of curvature might be twice as great. Under these conditions it is not possible, as one can readily see, that there can be any appreciable imperfection. The problem is therefore solved, as I said above.

(2) The impossibility of finding glass-works capable of furnishing large disks for mirrors, pointed out by Mr. Grubb, does not exist. We have in reserve at the Observatory a disk for a plane mirror of 1·22 m. diameter, weighing 650 kilos. The mirror just finished by the brothers Henry has a diameter of 40 inches, with a thickness of ·17 m.; this weighs 380 kilos. The glass-works of St. Gobain are prepared to furnish blocks weighing a ton, the diameter 58 inches, to anybody who will order them.

(3) The third point in Mr. Grubb's criticism has arisen from some error in calculation. Mr. Grubb makes me say that it is necessary to give the mirror a thickness equal to 1/5 of the diameter, and then making some calculations with this false datum, he finds that the mirror necessary for an equatorial coudé of 27 inches would weigh 8½ tonnes, and it is this result that misleads him. Here are the facts. I have never said that the thickness should be ·18 of the diameter. I have given ·18 as a *maximum*. Allow me to quote textually what I have said (*Journal de Physique*, August 1883): "Des recherches effectuées avec des miroirs de 0·08 m. m'ont démontré que pour prevenir dans un miroir toute déformation causée par la flexion ou un leger serrage, il faut que l'épaisseur du verre soit 0·18 du diamètre. Peut être avec des miroirs plus grands sera-t-il possible de réduire notablement cette épaisseur; en tout cas, la fraction 0·18 doit être considérée comme un maximum."

In my equatorial coudé for example, the mirror has a thickness equivalent to 1/6 of the diameter. In taking 1/7 for a mirror of 38 inches destined for an object-glass of 27 inches, one has still nothing to fear, for its weight would scarcely reach 250 kilos., that is to say, the half of the weight indicated by Mr. Grubb. For an instrument which weighs already between 8 and 9 tonnes, this addition of 250 kilos., or of 280 kilos. if we adopt the proportion of 1/6, is so small as not to be worth mentioning. From a mechanical point of view the displacement of the cylinder carrying mirrors of 250 kilos., or even a tonne, considering both the movement and the stability of the installation, does not offer the least difficulty. It is a mechanical problem so elementary that not only the first-class artists of all countries but even ordinary constructors would be able to solve it without any great effort of intelligence. I am only astonished that a man of Mr. Grubb's reputation should have stopped to consider such a detail.

(4) We now come to the question of expense. I am curious to know whence Mr. Grubb could have got his information, because it differs so absolutely from the facts. In spite of the addition of two supplementary mirrors, the price of the new instrument is less, or at all events not greater, than an ordinary one. The simplicity of the construction is such that the saving in the mechanical part covers the expense of the optical one. As I have already pointed out in the *Comptes Rendus* in 1871 and 1873, and in the *Journal de Physique* already quoted, the considerable expense of rotating domes, &c., is entirely avoided. I am greatly astonished, therefore, that Mr. Grubb makes on this point, so thoroughly studied, an objection so little founded. If he had, moreover, looked at the drawing which I published in the *Journal de Physique* of last year, he would have seen that it is almost identical with that which he has communicated to the Dublin Society, so far as the general arrangements for sheltering the observer and instrument are concerned. M. Gautier has been good enough to furnish me with the prices.

Dimensions Inches	Ordinary Equatorial Francs	Equatorial Coudé Francs
12	48,000	44,000
18	81,000	79,000
27	183,000	183,000

These prices are for instruments of the most complete kind.

The objects which I wished to attain were (1) to realise an instrument more stable than the ordinary ones, and to render possible the measurement of large angular distances; (2) to establish an arrangement which permits the astronomer to explore the whole sky and to regulate himself, with the most perfect convenience, all the movements of his apparatus; (3) to avoid the necessity of those monumental domes, of which both the building and the movement are always so costly; (4) to realise an instrument which, in spite of the introduction of two supplementary mirrors, would be optically more perfect. Indeed, being able to give the telescope a much greater focal distance than in the common large instruments, the achromatism may be rendered more perfect. I believe that I have succeeded in satisfying these various conditions, and that I can appeal to the judgment of several of the most eminent astronomers who have studied the instrument. Mr. Grubb makes a last reproach rather curiously. He is astonished that I have not as once applied the new system to the construction of a large instrument, for he adds, "No one finds any difficulty in working an equatorial of 11 inches." I do not know whether this opinion of Mr. Grubb is based on his personal experience, but I do know that all astronomers do not share his optimism on this point. To cite only one instance. In all the observatories where the discovery of comets or small planets is in question, telescopes of 6 or 7 inches aperture at the outside are employed. Continued work of this kind with a larger instrument is accompanied with fatigue. Now in my instrument, whatever be the nature of the research, a precious economy of time and energy is secured. If we have not in Paris a larger telescope on my plan, I must say that my regret is greater than that of Mr. Grubb, and that the lack of it does not depend on me.

In a subsequent letter I propose to discuss Mr. Grubb's counter proposal. M. LŒWY

Paris Observatory, April 10

On the Motion of Projectiles

EXPERIMENTS made in 1866 showed that the resistance of the air to the motion of projectiles varied only slightly for such forms of heads as were likely to be used in practice, and that it was of no importance whether the apex of the shot was pointed or rounded off.

From what I have said (NATURE, vol. xxix. p. 527) it is evident that before we can calculate the trajectory of shot we must know something of the quality of the gun from which the shot is supposed to be fired. For if trajectories of shot fired from the experimental guns were calculated by the use of the tabular values of K_v, it is plain that the calculated ranges would err in *excess* for the 3-, 7-, and 9-inch guns, and in *defect* for the 5-inch gun. As Mr. Ristori, using tabular coefficients, finds his calculated less than his experimental range, it may be that his gun gave a degree of steadiness above the average, as the 5-inch gun did. It is also necessary to be correctly informed of the exact *initial direction* taken by the shot, because, owing to the recoil of the gun, there is a "jump," which gives a greater elevation to the direction taken by the shot than the elevation of the axis of the gun. It is also a difficult matter to obtain the correct *initial velocity* of a small-arm bullet. For I am assured on the highest authority that the cotton threads of which my screens are composed, would be likely to cause unsteadiness in the motion of a small bullet, and if so, the measured velocity would be lower than the velocity of the undisturbed bullet. And if wire screens were used, the evil would be increased. From the excellent work done by Robins with a *small* ballistic pendulum, I am disposed to think that that instrument might be advantageously used in experiments with *small*-arm bullets.

As my tabular values of K_v were determined from the average results given by 3- to 9-inch shot, I did not venture to put them forward as being applicable to the calculation of the motion of small bullets. But recently Major McClintock, R.A., Assistant Superintendent Royal Small-Arms Factory, has used them for that purpose. He says:—"The accuracy of rifle-bullet trajectories calculated by means of Prof. Bashforth's tables, has been tested by firing a large number of rounds through paper screens placed at different points along the range. The rifle used in the experiment was the Martini-Henry, and the screens were erected at intervals along a 500-yards and a 1000-yards range. The result of the experiment was most satisfactory, the mean heights of the bullet-holes in the screens agreeing closely with the heights found by calculation."

As is well known, guns vary greatly in the degree of steadiness they impart to elongated shot, and this often changes with the initial velocity of the shot. It is important, therefore, to have a ready way of changing the tabular coefficients K_v in the ratio of $1 : \kappa$, when the coefficients will become κK_v, where κ is a constant for that round. In the calculation of the general tables, and in using the tables of values of integrals denoted by X, Y, and T, we have to deal with the product $\frac{d^2}{w} \times (\kappa K_v) =$

$\left(\frac{d^2}{w}\kappa\right) \times K_v$. Hence, if we calculate the value of $\left(\frac{d^2}{w}\kappa\right)$ at first, we may proceed without further change to use the general tables, or to calculate trajectories, using the tabular values of K_v, just as when no change is required in the value of the tabulated coefficients. For the 3-, 5-, 7-, and 9-inch guns, the value of κ, in the cases we have considered, would be 1·08, 0·92, 1·05, and 1·08 respectively. There was one case where the studs did not act, when K_{950} was found to be 335·1 instead of 75·0, which gives $\kappa = 4·47$. The smaller the value of κ the steadier will be the motion of the shot. Mr. Ristori might calculate another range, using $\kappa = 0·92$ given by the 5-inch gun, if he be satisfied that he has got the correct initial velocity and initial direction of the shot. If the calculated and measured ranges did not now quite agree, the remaining correction of κ might be found perhaps with sufficient accuracy by proportional parts. This seems to be the best way of expressing the degree of steadiness of shot when they are so light as to have their motion disturbed by cutting the threads of screens. But for heavy shot the most direct way is to fire through equidistant screens as already explained.

When I made experiments with low velocities in 1879, I was furnished with some range tables of the 6·3-inch Howitzer, where, it was said, my coefficients did not give correct results. As the difficulty in obtaining good results increases as the velocity decreases, I took the trouble to make a thorough comparison between the calculated and experimental results in the above case. I also made use of some German range tables in the same way, where the value of $d^2 \div w$ was only a trifle larger. The results of these comparisons may be found at pp. 45–49 of my Final Report, 1880, which appear to me quite satisfactory.

So long as there are guns good, bad, and indifferent, it is clear that no single set of coefficients can give ranges suited to all cases. But ranges, &c., calculated by the help of my coefficients, may serve as a standard of comparison applicable to every case, and so give a measure of the steadiness of the shot.

April 23 FRANCIS BASHFORTH

The Dry and Wet Bulb Thermometers "Froude"

A SO-CALLED thermometer "froude" has been used in France for many years, and its use, on special occasions, has gradually extended to other countries. It consists of an ordinary thermometer fastened to a string two to four feet in length. If such a thermometer be swung through a circle whose radius is the length of the string, it is evident that it will attain the temperature of a large mass of air unless the results are vitiated by friction with the air, oxidation, centrifugal action, or other causes. Careful comparisons, at high and low velocities, with a thermometer properly exposed, have given entirely reliable results.

Some time ago the writer attempted to use this instrument as a wet bulb with such results that it was decided to fasten two thermometers together, one with its bulb one and a half inches below the other. The latter may be easily wet by immersion without wetting the dry. This arrangement has worked admirably, and has been in constant use the past winter in determining temperature and humidity conditions both in city and country, in courts and rooms. Every one who has undertaken humidity observations with a wet bulb thermometer, especially in cold calm weather, has found it very difficult to obtain good results even after an hour's waiting after wetting. With this instrument it is an easy matter in every instance to obtain an absolutely correct result in two or three minutes. This is shown by the fact that repeated wetting and swinging will give the same result as often as tried. If ice is on the bulb, it is best, after swinging for several observations, or until the clear glare of ice has gone, to wet in water above freezing so as to remove the old ice and form a new coat. Distilled water should also be used if possible.

With this instrument it has been found that, in order to get even approximate results of humidity above grass ground, in clear calm weather, with temperature below freezing, the observation must be made upon a knoll, never in a valley or upon a plain with rising ground on any side. It has also been found that under the above conditions in the morning a height of twenty to thirty feet is essential, even upon a knoll, in order to obviate the effect of the gradual accumulation through the night of damp air above sod. H. A. HAZEN

April 14

Extraordinary Darkness at Midday

THE extraordinary darkness that occurred here suddenly on the morning of the 26th is deserving of record, as being the most intense that is remembered by any of the inhabitants.

The early morning was bright, and no change was noticed until close upon 11 a.m., when the sky became rapidly darker in the west-south-west. The wind was blowing from the north-east at 11 a.m. with a velocity of five miles an hour, and it scarcely changed at 11.40, when it increased to seven miles an hour, and veered at once to south-west, and then moved more slowly round through west and north, back again to east at 1 p.m., when its velocity was only three miles an hour.

At 11.30 the darkness was so great that it was found impossible to read even bold print (small pica) close by the window, and at this time a dense black cloud with a slightly yellowish tinge hung over the south-west sky; the blackness being most intense at 10° above the horizon. At 11.35 it became somewhat lighter, and at 11.40 the rain began to fall, and in forty minutes 0·114 inch of rain-water was collected in our rain-gauges, the whole being almost as black as ink, and full of fine carbon in suspension. Hail that fell a mile off to the south-west by south, and both hail and snow that fell on the hills two miles to the west, were also black. At Preston, fourteen miles to the south-west, the darkness was very marked, but five and a half miles to the north-east nothing very particular was noted.

Stonyhurst Observatory, April 28 S. J. PERRY

Intelligence in Animals

I THINK it was about the year 1844 that the Duke of Argyll desired my late father, his factor, to preserve game in the district of Kintyre, Argyllshire. If any steps in this direction had been taken by other proprietors, they were very irregular. My memory goes back to about 1846 and 1848, and at that time the grouse of Kintyre "sat like stones"—they might be shot to dogs from the first to the last day of the season; in fact it was often difficult to get the birds up. With this preservation, grouse increased enormously—and therefore the food supply of the people—to such an extent that the late Sir John Cuningham and my father shot, on one 12th of August, seventy-two brace of grouse. Sir John was a very old man, and insisted on loading his own gun, an old muzzle-loader. My father never shot hard. Now I do not believe any two men with two guns and loaders could do this in the same district with all the improvements in arms and dogs; whilst I have heard my father say that seven brace was a good bag when he was young, before game-preserving.

Grouse yet sit pretty well in Kintyre, and I believe this is the case because it was one of the last districts to preserve and shoot; but the birds are every year becoming wilder, and now in the month of September it is useless to take dogs on the hill, and for two years we, like others, have had to drive them.

I account for this by an alteration in instinct, and I am as sure as any one can be, from observation and the opinion of competent persons, that it is *progressive instinct in successive generations*. Formerly the great enemies of the grouse were ravens, that took their eggs and young birds; foxes, polecats or martin cats, and wild cats, that took them at *night* on the ground; and hawks, that took them on the wing during the day. When man stepped in and altered the balance of Nature, the

Bird that up and flew away,
He lived to breed another day.

No hawk was there to knock him down. He found from experience that flying away before man and his dog came near gave him safety; and his children that inherited the wit or instinct or power of turning heather into nerve-force or intelligent thought—or whatever the straw-splitters like to call it—lived; whilst his brother, that inherited the qualities which kept him hiding in the heather, was shot when forced up.

I had this summer ample corroboration of this theory. About eight years ago I was shooting in the island of Rum; the grouse were not preserved and were extremely tame, so tame in September and October that I had to run after them to make them take the wing, and it was new to dogs. Last year I again shot in the island, and I observed the same tameness in one part of the island, but in another district I observed the grouse were larger, darker, and much wilder. I was puzzled with this until I found out that the late tenant had three years before turned down some English grouse, and in the district where they were so turned down the grouse were very wild.

Knockrioch, April 28 DUNCAN STEWART

IN NATURE (vol. xxix. p. 596) there is a letter signed James Graves, in which he says, "as to the magpie or any other bird being able to fix dates exactly to the day, it is unproved and incredible." I do not know what may be the case in regard to birds-nestbuilding, but I can give two instances of the regularity with which birds arrive at certain localities *en route* northward, whatever may be the state of the weather. During a ten years' residence on the shores of Hudson's Bay, the first Canada goose of the spring migration was seen and generally shot on April 23. At Toronto on Lake Ontario, large flocks of a pretty little plover called the "black-heart," from a black patch on its breast, pass along the islands, flying northward, on St. George's Day (April 23), and are seldom or never seen even a day before or a day after that date. The poor little birds have a sad time of it for six or eight hours, as a number of sportsmen go out for the occasion and knock them down by the half-dozen or more at every shot. In this case, as in the other, wind and weather appear to cause no difference JOHN RAE

4, Addison Gardens, April 25

THE ABSORPTION OF WATER BY PLANTS

AN ingenious instrument has lately been described by Dr. J. W. Moll (*Archives Neerlandaises*, i. xviii.) under the name of the Potometer. It is a modification of Sachs' apparatus for determining the amount of water which a cut branch absorbs in a given time. I have been for some years in the habit of using a form of Sachs' instrument, differing in principle from Moll's apparatus, but resembling it in being especially adapted for making observations at short intervals of time. As the subject of transmission of water through wood is now attracting attention among physiologists, it seems worth while to describe my instrument.

A short piece of thick indiarubber tube is slipped over the cut end of a branch and firmly attached to it by wire ties; the other end of the rubber tube being securely fitted to a glass tube which is filled with water. The other end of the glass tube is closed by an indiarubber cork through which passes a coarse thermometer tube. The apparatus is now fixed so that the free end of the thermometer tube dips into water. As the leaves evaporate the water in the glass tube is sucked up by the cut end of the branch, the loss being constantly made up by a current flowing in through the thermometer tube. If then we can estimate the rate of this current we shall know the rate of absorption of water. This is very simply done by allowing, for a few seconds, the thermometer tube to suck in air instead of water; when a column of air a few millimetres in length has been drawn in, the end of the tube is again immersed in water, and the bubble travels rapidly along the thermometer tube, when its speed is measured by means of a chronograph.

This method appears no doubt to be a rough one, and is open to objections; but I believe that it does not give rise to serious errors, and it certainly demonstrates extremely well small changes in the rate of absorption by a cut end of the branch. By means of my instrument observations can be made at very short intervals; for instance, four readings were taken in 1′ 50″; it is therefore well adapted for observing rapid changes in the rate of absorption.

I reserve a full discussion of the merits and demerits of the instrument for a later publication.

Experiments, April 1884.—When a branch is first fitted to the instrument the rate of absorption is extremely rapid, owing to causes which need not here be considered, but after a time the rate of absorption (which diminishes with great rapidity) becomes constant. A branch of Portugal laurel (*Cerasus lusitanica*) was cut at 9 30 a.m., and was not fitted to the apparatus until 10.15 a.m.

The following table shows clearly the rapid decrease in the rate of absorption:—[1]

Times h. m.	Rate of Absorption
10 18	71
20	53
25	40
11 14	26
35	25
52	25

Sachs has called attention to the diminution in the absorption which occurs when cut branches are placed in water, and has shown that the absorbing power can be renovated by cutting a fresh surface at the base of the branch. This effect is well shown with my instrument.[1]

The above-mentioned branch of Portugal laurel which had been placed in water at 9.30 a.m. gave a relative rate of absorption of twenty-four at 12.28; at 12.30, between 6 and 7 cm. were cut off, and the branch was again fitted to the machine, the operation lasting one and a half minutes.

Time p.m. h. m.	Rate of Absorption
12 28	24
30	fresh surface cut
31½	branch replaced
33	35
35	30
39	28
45	26
54	26

When the rate of absorption has become constant, any variation in dampness or dryness of the air causes variations in the transpiration of the leaves, and therefore in the rate of absorption. These changes are well shown by my instrument. The following experiment, made with a branch of Portugal laurel shows the amount and rapidity of the increase in absorption caused by exposing the leaves to the sun shining through window-glass:—

Time a.m. h. m.	Rate of Absorption
10 44	14
49	14
55	14
11 0	15
5	15
6½	14
Blind drawn up	
7½?	14
9	20
12½	27

Thus in six minutes the rate of absorption had nearly doubled. A similarly rapid effect is seen when the sunlight is cut off, when the rate of absorption falls.

Time h. m.	Rate of Absorption
12 5	33
10	32
10½	blind down
12½	27
19½	20
25	19
29	18

That is, the rate of absorption diminished in the proportion of 100 : 56 in twenty-four minutes, when the sunlight was cut off. In the same way the effect of opening a window and thus increasing the evaporation for the leaves, is a once visible in increased rate of movement in the bubble.

Cut Stem of Ivy

Time a.m. h. m. s.	Rate of Absorption
10 33 0	32
11 0 0	31
9 0	window and door opened
10 40	34
11 30	37
12 0	37
18 0	33
19 0	window and door shut
21 30	31
22 30	29
40	31

[1] In this and the following tables I have not given the actual quantities of water absorbed, merely the relative rates of absorption.

[1] It need not here be discussed whether the particular phenomenon her described is the same as that described by Sachs.

Effect of Disturbance.—The fact observed by Baranetzky, that a small disturbance, such as a slight shake, increases the transpiration of the leaves, is also easily seen, and my observations show that in some cases the effect may be very transitory. It need not occur in the use of my instrument, since the plant remains quite untouched, the only necessary movement being the removal and replacement of a vessel of water to allow the entrance of a bubble.

Effect of Sudden Diminution of the Evaporating Surface.—I have been astonished to find with what rapidity the rate of absorption diminishes when the evaporating surface is diminished by cutting off a twig from the branch under experiment.

A branch of Portugal laurel was absorbing (April 10) with great regularity.

Time p.m. h. m. s.	Rate of Absorption
5 5 0	23
47 0	23
48 40	a small branch cut
49 15	21
50 30	20
52 0	21
58 0	20
6 4 0	20
11 0	20
12 0	another branch cut off
20	18
13 0	17
14 40	16
26 0	16
35 0	16

When the first branch was removed nearly the whole of the permanent diminution was visible in 35″; in this case the distance from the base of the branch to the place where the small branch was severed was 28 cm.

In the second experiment half the permanent effect was produced in 20″; and here the distance of the cut-off twig from the cut end of the main branch was 45 cm.

But far more remarkable results were obtained when a long stem of ivy was used for the experiment.

A stem of ivy was removed from the tree on which it grew on April 13, and was placed with its cut end in water until the following day, when it was fitted to the apparatus.[1]

April 14.—The rate of absorption remained fairly constant from 10.30 to 11.45 a.m., when the first branch was removed.

Time a.m. h. m. s.	Rate of Absorption
10 33 0	32
11 42 0	31
45 0	branch cut off
15	29
46 20	23
53 0	26

The branch which had been cut off left the main stem at a distance of 13 feet 3 inches from the basal end, so that change in the rate of absorption was transmitted at the rate of 0·88 feet per second.

In a second trial the following results were obtained:—

Time h. m. s.	Rate of Absorption
3 1 0	23
6 0	23
11 30	23
13 0	stem cut
15	18
14 0	17
15 30	15
18 0	15

The point at which the stem was severed was 16 feet 5 inches from the basal end, so that here a change in absorption travelled at the rate of 1·1 foot per second. The same result followed on two other occasions, but here the rates of transmission were slower—

15 feet 5 inches in 30″,
9 feet 10 inches in 30″.

In the latter of these two cases the part removed was not a branch of the stem, but a branch belonging to a neighbouring stem which had grown into lateral union with it, so that here the transmission of the change must have taken place laterally from the branch to the stem, and then longitudinally along the latter.

Effect of partly severing the Branch.—My instrument is well adapted for testing the transmitting capacity of a branch which has been partly cut through. I have been much surprised at the fact that cuts to the depth of half or more than half the diameter of the branch produce practically no diminution in the rate of absorption. Indeed a slight increase is often visible owing to the disturbance which must occur when the branch is cut with the saw.

A branch of yew ·55 inch in diameter was sawn (A) to the depth of ·25 inch, (B) so deep that the bridge of *wood* through which the water had to pass was not more than ·1 inch in thickness in radial direction.

Time p.m. h. m.	Rate of Absorption
3 26	99
32	99
34	cut A made
35	98
40	103
47	101
4 3	99
37	99
38½	cut B made
40	100
43	97
46	100
50	100

It was only when the bridge remaining after cut B was narrowed, by sawing on both sides at right angles to the former direction, that the rate of absorption fell. The same thing was shown in another branch of yew, the woody part of which was 10 mm. in diameter, and which was sawn to a depth of 8 mm., leaving a bridge 2 mm. thick in radial direction. Even this deep section did not diminish the rate of absorption. With the Portugal laurel the same thing was observed; and here the possibility of recovery from a temporary diminution in absorption was shown in two cases.

The branch with its bark on measured 11 mm. in diameter, and it was traversed by an excentric cylinder of old brown wood 1·8 mm. in diameter.

The following figures give the result of section:—

Time a.m. h. m.	Rate of Absorption
11 0	18
9	18
14	cut A
16	16
20	18
30	17
12 0	17
6	18
8–9	cut B
10	18
11	19
17	17
30	18
35	cut C
36½	9
38	9
42	10
48	12
55	14
p.m. 1 15	16

[1] The stem was fixed so that its distal end was some few feet above the base immersed in water.

It will be seen that the two first cuts produced no effect comparable to that caused by C. Cut A was 3 mm. deep, cut B was also 3 mm. deep on the opposite side, so that, after B had been made a bridge, 5 mm. in radial direction remained; nevertheless the rate of absorption was undiminished. Cut C was made by increasing B to the depth of 5 mm. from the bark, so that the bridge of more or less central wood finally left was 3 mm. in radial thickness, and even then the diminution was only temporary. The cuts were made about 7 cm. from the basal end, and the same distance from the first branch. Another branch of Portugal laurel showed the same thing. The wood of the branch at the point of section was about a centimetre in diameter, and contained a large proportion of old brown wood. The external envelope of white wood was cut away with the exception[1] of a bridge measuring roughly 3 × 3·5 mm. in cross section.

The result is shown in the following table:—

Time p.m. h. m.	Rate of Absorption
1 34	15
2 13	15
16	cut
19½	10
21½	11
26	13
32	14
39	13
47	14
53	15

Here again we have a diminution followed by gradual rise.

When the little bridge of younger wood was severed, the fall in rate of absorption was rapid.

Time p.m. h. m.	Rate of Absorption
5 27	16
28½	bridge severed
32	0·12
47	0·08

Thus the absorption fell to one-twentieth of the original amount; that it did not quite cease may be accounted for by the fact that the younger circumferential wood was not completely cut through.

My apparatus would be also suitable for such experiments as those of Dufour (*Arbeiten d. Bot. Inst. in Würzburg*, 1884, Band iii.), in which he showed that sharply bending a stem, such as a hop-bind, does not prevent the passage of the water of transpiration, whereas water could not be mechanically forced through the bent stem. Dufour also repeated Hales' experiments in which the transpiring branch was cut half through on two opposite sides, the points of section being an inch or two apart. When this had been done, so that the continuity of all *cavities* of vessels and cells was broken, he found that the transpiration-stream could still pass, because the continuity of the cell-*walls* remained unbroken. I give a single experiment of this kind to show that my instrument is well adapted for such work (April 15):—

Time h. m.	Rate of Absorption
11 32	25
34	25
36	25
37½	first cut
39	22
49	24
55	second cut
12 2	0·84
22	0·69

Both cuts penetrated to the centre of the branch. The first was one and a half inch from the base, the second half an inch below the first cut, and on the opposite side of the branch.

Dufour's experiments would seem to show that the great depression in absorption which occurred on making the second cut may have been only a temporary phenomenon; this and other kindred questions I hope soon to be able to work out. FRANCIS DARWIN

Cambridge, April 17

[1] The young wood was not well severed, and a small amount remained in continuity.

WHAT IS A LIBERAL EDUCATION?[1]

I DO not intend, in the present paper, to enter upon the disputed question between the advocates of classical culture on the one hand, and those of scientific training on the other; because it seems to me that the line on which the two parties divide is not that which really divides the thought of the day. If we look closely into the case, we shall see that the objects of a higher education may be divided into three classes, instead of the two familiar ones of liberal and professional. In fact, what we commonly call a liberal education should, I think, have two separate objects. With the idea of a professional education we are all familiar: it is that which enables the possessor to pursue with advantage some wealth-producing specialty. Although, in accordance with well-known economic principles, it is designed to make the individual useful to his fellow-men, the ultimate object in view is the gaining of a livelihood by the individual himself. On the other hand, the object had in view in what is commonly known as culture is not the mere gaining of a livelihood, but the acquisition of those ideas, and the training of those powers, which conduce to the happiness of the individual. From this point of view culture may be considered an end unto itself.

The third object which we have to consider is only beginning to receive recognition in the eyes of the public. It is the general usefulness of the individual, not merely to himself and to those with whom he stands in business relations, but to society at large. Modern thought and investigation lead to the conclusion, that man himself, the institutions under which he lives, and the conditions which surround him, are subject to slow, progressive changes; and that it depends very largely on the policy of each generation of mankind whether these changes shall be in the way of improvement or retrogression. During the next fifty years all of us will have passed from the stage of active life, and the course of events will be very largely directed by men who are still unborn. The happiness of those men is, from the widest philanthropic point of view, just as important as the happiness of those who now inhabit the earth; and, in the light of modern science, we now see that that happiness depends very largely upon our own actions. We thus have opened out to us an interest and a field of solicitude in which we need the best thought of the time. The question is, What form of education and training will best fit the now rising generation for the duty of improving the condition of the generation to follow it?

Let it be understood that we are now speaking, not of the education of the masses, but of that higher education which is necessarily confined to a small minority. So far as I am aware, that fraction of the male population which receives a college education is not far from 1 per cent. To that comparatively small body we must look for the power which is to direct the society of the future, and by their acts to promote the well- or ill-being of the coming generation. Our duty to that generation is to so use and train this select body as to be of most benefit to the men of the future. What is the training required? I reply by saying that I know nothing better for this end than a wide and liberal training in the scientific spirit and the scientific method. The technicalities of science are not the first object; and, so far as they are introduced, it is only

[1] From *Science*.

as media through which we may imbue the mind with certain general and abstract ideas. If called upon to define the scientific spirit, I should say that it was the love of truth for its own sake. This definition carries with it the idea of a love of exactitude—the more exact we are the nearer we are to the truth. It carries with it a certain independence of authority; because, although an adherence to authoritative propositions taught us by our ancestors, and which we regard as true, may, in a certain sense, be regarded as a love of truth, yet it ought rather to be called a love of these propositions, irrespective of their truth. The lover of truth is ready to reject every previous opinion the moment he sees reason to doubt its exactness. This particular direction of the love of truth will lead its possessor to pursue truth in every direction, and especially to investigate those problems of society where the greatest additions to knowledge may be hoped for.

Scientific method we may define as simply generalised common sense. I believe it was described by Clifford as organised common sense. It differs from the method adopted by the man of business, to decide upon the best method of conducting his affairs, only in being founded on a more refined analysis of the conditions of the problem. Its necessity arises from the fact that, when men apply their powers of reason and judgment to problems above those of every-day life, they are prone to lose that sobriety of judgment and that grasp upon the conditions of the case which they show in the conduct of their own private affairs. Business offers us an example of the most effectual elimination of the unfit and of "the survival of the fittest." The man who acts upon false theories loses his money, drops out of society, and is no longer a factor in the result. But there is no such method of elimination when the interests of society at large are considered. The ignorant theoriser and speculator can continue writing long after his theories have been proved groundless, and, in any case, the question whether he is right or wrong is only one of opinion.

I ask leave to introduce an illustration of the possibilities of scientific method in the direction alluded to. Looking at the present state of knowledge, of the laws of wealth and prosperity of communities, we see a great resemblance to the scientific ideas entertained by mankind at large many centuries ago. There is the same lack of precise ideas, the same countless differences of opinion, the same mass of meaningless speculation, and the same ignorance of how to analyse the problem before us in the two cases. Two or three centuries ago the modern method of investigating nature was illustrated by Galileo, generalised by Bacon, and perfected by Newton and his contemporaries. A few fundamental ideas gained, a vast load of useless rubbish thrown away, and a little knowledge how to go to work acquired, have put a new face upon society. Look at such questions as those of the tariff and currency. It is impossible not to feel the need of some revolution of the same kind which shall lead to certain knowledge of the subject. The enormous difference of opinion which prevails shows that certain knowledge is not reached by the majority, if it is by any. We find no fundamental principles on which there is a general agreement. From what point must we view the problem in order to see our way to its solution?

I reply, from the scientific standpoint. All such political questions as those of the tariff and the currency are, in their nature, scientific questions. They are not matters of sentiment or feeling which can be decided by popular vote, but questions of fact, as effected by the mutual action and interaction of a complicated series of causes. The only way to get at the truth is to analyse these causes into their component elements, and see in what manner each acts by itself, and how that action is modified by the presence of the others: in other words, we must do what Galileo and Newton did to arrive at the truths of Nature. With this object in view, whatever our views of culture, we may let science, scientific method, and the scientific spirit be the fundamental object in every scheme of a liberal education.

S. NEWCOMB

THE KRAKATOA ERUPTION[1]

THE inquiry, instituted in consequence of a Government resolution of October 4, 1883, into the nature, the extent, and the consequences of the volcanic eruptions of Krakatoa, has led to various remarkable results of which a short account is given here. A detailed report is in course of preparation, but will not appear for some months, as the making of numerous illustrative maps and plates will take much time. The inquiry did not extend solely to the islands of the Straits of Sunda, but also to the coast countries of the Lampong districts, Bantam and Batavia, which were partly or entirely destroyed. In the Straits of Sunda the islands of Merak, Toppershoedje, Dwars in den Weg (Thwart the Way), Seboekoe, Sebesi, Lagoendi, Krakatoa, Taboean, Prince's Island, the Monnikrotsen (the Monk's Rocks), and Meeuwen Island (Mew's Island), were visited; further, the coast-strip from Ketimbang to Kalianda, and inland as far as Kesoegihan, besides the foot of the Radja Bassa; the coast of Hoeroen to Telok Betong, and the environs of the capital; the southern part of Semangka Bay (the northern part was inaccessible through pumice-stone), the kampoengs Tampang and Blimbing, near the Vlakken Hoek, Java's First Point (Java Head), and the coasts of Tjiringin and Anjer to Merak. The voyage, which lasted seventeen days, was made by the *hopperbarge* (small steamer) *Kediri*, commander 't Hoen, given for the inquiry by the temporary chief of the Batavian Harbour Works. About the causes of eruptions there is usually not much to be said, yet in this case something has been ascertained. Krakatoa, namely, lies with a few other volcanoes on a rent or fissure in the crust of the earth which runs across the Straits of Sunda, and of which I indicated the probable existence for the first time three years ago. Along such a fissure little shiftings of the earth's crust are possible, by which a pressure is exercised upon the molten substances below the crust. It is also possible that along such a rent—however tightly closed by the neighbouring stone-layers—the water may more easily than elsewhere flow to the regions under the earth. If this water comes in contact with the molten substances, steam at high temperature and high pressure is formed, and this steam may be considered as the chief motor of most, if not all, volcanic eruptions.

Many circumstances, therefore, combine to make eruptions take place in preference near fissures, provided water (either rain or sea-water) can penetrate in sufficient quantity. We must conclude from the 200 years' quietude of the volcanoes in the Straits of Sunda that the water affluence during that time was but small, and only became larger within the last years. Now it happens that during the last years a great many earthquakes took place along this fissure, of which the lighthouse on "Java's First Point" in particular suffered greatly. The most violent earthquake took place September 1, 1880; the upper part of the tower was rent, and had to be broken off afterwards. These earthquakes were probably the result of subterranean subsidences, and I think I may assume that through those subsidences modifications took place along the fissure through which the sea-water could ooze in greater quantity than before. Within the three last years the pressure of the steam formed became sufficiently strong to force the lava, out of the much deeper-lying lava strata, upwards through the crater of Krakatoa, and the eruption took place when, at last, the violence of the steam was enabled to force its way through the lava to the crater and the surface. The steam carried with it a

[1] Translation of a Short Report on the Eruption of Krakatoa on August 26, 27, and 28, 1883.

quantity of lava, which was mostly shot as fine dust out of the crater. The porous nature of the ejected substances —pumice-stone was almost the only substance formed—is doubtless to be ascribed to the steam, which was blown with great force through the lava. I must keep the more detailed description of the way in which the eruption proper was prepared and took place for a future time, as drawings are requisite for a right understanding of the matter. I must still observe here, however, that through the Krakatoa eruption our notions about the shape and extent of subterranean regions will probably be much modified. If it may be assumed that there exists a connection between our eruptions, the heightened activity of the volcanoes in the Indian Archipelago since that time, and the earthquakes in Australia which took place simultaneously with and succeeded the eruptions of the last days—in any case a remarkable coincidence—then much larger dimensions will have to be allowed to those regions than the present geologists are accustomed to assign to them.

Krakatoa is the only point which has been active. There are reports that Sebesi and the Radja Bassa have also shown activity, but this is inaccurate.

Of the old Krakatoa there is no detailed survey; the English and Dutch sea-charts, both on a small scale, besides a couple of sketches taken by Buijskes in 1849, and by me in 1880, alone give some idea of the surface-formation of the island. From the two sketches may be seen that the island had three tops—the northern, called Perboewatan (in some reports Roewatan), was the lowest of the three, and showed streams of lava on various sides; this is the point which first began to be active in May 1883, and which probably also ejected pumice-stone in 1860. The centre top bore the name of Danan, and was active also in August 1883. The southern peak, the mountain Rakata properly speaking (which was corrupted into Krakatoa), was by far the highest point of the whole island, and, according to the sea-chart, 822 metres high. This point is also an old crater, but was *not* active in 1883.

On May 20, 1883, the Perboewatan began suddenly to show signs of activity; that nothing was known before then of an approaching eruption must be ascribed to the fact that Krakatoa was uninhabited, and only visited occasionally by Lampong fishermen, who went no further than the coast. Otherwise it would seem inexplicable that no previous signs of it should have been noticed. The eruptions lasted with various degrees of violence, and with intervals, till August 26; while latterly also the crater of Mount Danan became active. Though in themselves not unimportant, these eruptions were insignificant compared to what followed. On August 11 trees were still growing on the peak, so that the destruction of vegetable life was then still limited to the immediate neighbourhood of the craters. On the 26th the explosions much increased in violence, and they reached their maximum on the 27th, at 10 a.m. They then diminished in strength, but lasted still the whole night of Monday to Tuesday, till they suddenly ceased on the 28th, at about 6 a.m.

About the eruptions from May till August 26 little of importance has, on the whole, become known; all I have been able to collect will be mentioned in the detailed report.

The eruptions of August 26 and 27 were accompanied by violent detonations and air vibrations. During those days almost incessantly a rumbling sound was heard which resembled the noise of thunder at a distance, the explosions properly speaking were accompanied by short detonations which can best be compared to heavy cannon shots, but the most violent detonations were still shorter and more rattling, and cannot be compared to any other sound.

The sounds of the explosions in May were heard in a north-west direction at Moeara Doea in Palembang, and at Bintoehan, in the division of Kauer in Benkoelen, respectively 230 and 270 kilometrès from Krakatoa; the transmission of the sound on August 27 surpasses, however, all which is known of the kind. The explosions were heard in Ceylon, in Burmah, at Manilla, at Doreh in the Geelvink Bay (New Guinea), and at Perth on the west coast of Australia, besides all the places which lie closer to Krakatoa than the above-mentioned. If a circle is drawn from Krakatoa with a radius of 30°, 1,800 geographical miles, or 3,333 kilometres, the circle will go exactly over the furthest points where the sound was heard. The furthest distance between the points east and west where the sound was heard is therefore 60° (the diameter of the circle) or one-sixth of the whole circumference of the earth. The surface of this circle, or rather of the spherical segment, comprises more than one-fifteenth of the surface of the earth. In historic times no eruption is known of which the sound was transmitted over such an enormous area. At the eruption of Tombora in Sumbawa, in 1815, the radius of the circle within which the sound was heard, was but half the size, namely 15°, the surface being therefore 3·93 times smaller.

If a circle with the same radius, namely 30°, is drawn round the earth, taking Amsterdam as the centre, the circle would have the following course. The northern point lies 82° north latitude, thus north of Spitzbergen; from there the circle runs to the middle of Novya Zemlya, thence along the Ural Mountains to Orenburg, Tiflis, Damascus, Jerusalem, Suez; crosses the Tropic of Cancer at about 15° east longitude from Greenwich, reaches the most southern point at 22° north latitude in the Desert of Sahara, crosses the Tropic of Cancer once more at 5° west longitude from Greenwich, runs close along Ferro, includes the Canary Islands and Azores, besides the greater part of Greenland, and runs back to the starting point north of Spitzbergen. In various places it was observed that the strongest detonations were heard at different hours, and also that in places in the neighbourhood of Krakatoa little or nothing was heard of the sound, whereas it was heard very distinctly in places further removed. Thus for example the loudest report was heard at Buitenzorg at a quarter to seven, at Batavia at half-past eight, at Telok Betong at ten o'clock on the morning of the 27th. This was caused principally by the direction of the wind; it appears clearly from the reports that the sounds were loudest on the side of Krakatoa whither the wind blew, and the fine ash particles were blown. But this does not yet explain the fact that the sound was sometimes better heard in places that were further off than in those that were nearer when those places lay in the same direction from Krakatoa, such as, for example, Anjer, Serang, and Batavia. This phenomenon is to be ascribed solely to the great quantity of ash particles which were present in the lower atmosphere. If one assumes for example the presence of a thick cloud of ashes between Krakatoa and Anjer, this would act on the sound waves like a thick soft cushion; along and above such an ash cloud the sound may be propelled very easily to further removed places, for instance Batavia, whereas at Anjer, close behind the ash cloud, no sounds or only faint ones would be heard. Other explanations, such as by the interference of sound, seem to me less probable though not entirely impossible.

Besides these sound vibrations, very long air waves were formed during the explosions, which did not manifest themselves by any sound, but had nevertheless an important effect. The most rapid of these vibrations communicated themselves to the buildings and walls of rooms, so that objects which hung on the walls or from the ceiling were set in motion. Thus at Batavia and at Buitenzorg, a distance of 150 kilometres from Krakatoa, the doors and windows began to rattle, clocks stood still, ornaments on cabinets fell down, and hanging lamps were

thrown out of their fastenings, and fell shattered to the ground with their chimneys and globes.

But not only at this distance was the air vibration perceptible. *At Batoe-Radja in Palembang (250 kilometres from Krakatoa) rents appeared in the pradjoerit's barracks at three o'clock in the night; even at Palembang, 350* kilometres from Krakatoa, several Government buildings had to be immediately vacated as a crash was feared; and even in the Alkmaar country in Pasoeroean, 830 kilometres from Krakatoa, the walls were rent in the house of the administrator and the machinist. All this was caused by air vibrations, *not* by earthquakes, for it is a remarkable fact that these have nowhere been observed with certainty in this eruption.

Finally in the most violent explosions, air waves of an astonishing length were formed. As the Meteorological Institute at Batavia no longer possesses a self-registering barometer, those waves would have passed unobserved at Batavia, had they not fortunately been recorded by the indicator of the gas-works. This apparatus is self-registering, and continually marks on a paper, wound round a turning cylinder, the pressure of the gas. As the large gasometer was set in motion on August 26 and 27 by the pressure of the air waves, these oscillations were marked by the indicator, and the line of pressure shows that day, not the normal curves, but a number of sharp points. As hour lines are marked on the paper, the time at which these oscillations occured can be accurately fixed, and if the time be deducted which the wave requires to travel from Krakatoa to Batavia, the moment is also known when the wave was formed, and the explosion took place (omitting a correction for the time which elapses between the moment of pressure on the gasometer and the moment this is recorded by the indicator, a lapse of time which is unfortunately not exactly known). The barometer experiments in Europe and America show that those large air waves possess almost as great a velocity as sound, from which it follows that they require seven minutes to travel the distance between Krakatoa and Batavia.

I have concluded from this that the most violent explosions took place at the following hours:—August 27, 5h. 35m., 6h. 50m., 10h. 5m., and 10h. 55m., Batavia time. By far the most violent of these four was the explosion of 10h. 5m. Then also an air wave was propelled from Krakatoa which spread in a circular form round this point as pole along the surface of the earth, and travelled no less than three and a quarter times round the whole circumference of the earth. The velocity was, as already observed, about the same as that of sound, although these were waves of a gigantic length (the length of the lowest sound waves being about 20 metres, that of the Krakatoa air wave more than a million metres).

The eruptions, which took place at first above the sea, probably became submarine about ten o'clock on August 27. Before that time only more or less damp ashes were ejected, after that also a large quantity of mud or mire, being volanic sand mixed with sea-water. The giving way of the northern part of the mountain must have preceded these submarine eruptions, as appeared from the time at which the large tide wave, which probably originated through this subsidence, overflowed the Vlakken Hoek. This catastrophe caused a great change in the group of islands of Krakatoa. To the north-west of Krakatoa lies Verlaten Island, to the north-east Long Island, and west of the latter lies the Poolsche Hoedje. This small island has disappeared, the two others still exist, and are even larger than before, through the ejected substances which have settled on and around the island; but the greatest change has been undergone by Krakatoa itself. The whole northern part with the craters Perboewatan and Danan, and half of the peak have sunk in the depths. There only remains the southern part of the peak, which has been cut in two from the very top, and forms on the north side a magnificent precipitous cliff more than 800 metres high. Through the downfall therefore a volcano rupture has been formed which is probably unique in the world. A coloured drawing of this remarkable rock will be added to the large report.

The size of Krakatoa was formerly 33½ square kilometres; of that 23 square kilometres have subsided, and 10½ square kilometres remain extant. But on the south and south-west side the island has been increased by a large ring of volcanic products, so that the size of New Krakatoa is now, according to our survey, 15¼ square kilometres. The size of Long Island was formerly 2·9 and is now 3·2 square kilometres. Verlaten Island has become much larger; it was formerly 3·7 and is now 11·8 square kilometres in size. Of the Poolsche Hoedje nothing remains.

In the place where the fallen part of Krakatoa once stood there is now everywhere deep sea, generally 200, in some places even more than 300 metres deep. It is remarkable that in the midst of this deep sea a rock has remained which rises about 5 metres above its surface. Close to this rock, which is certainly not larger than 10 metres square, the sea is more than 200 metres deep. It is like a gigantic club, which Krakatoa lifts defiantly out of the sea.

The volcanic products of the preceding year consist almost exclusively, as we have already said, of pumice-stone; only here and there among the pale gray material a solitary piece of darker coloured steatite or a vitreous piece of obsidian appears. Although the stone masses in the crater were doubtless liquid, a stream of lava could nowhere pour down, because everything was shot out of the crater in larger and smaller pieces, and generally in powder.

The chemical composition of the ejected substances is not yet sufficiently known, but from the analyses that have hitherto been made it would appear that all the substances do not contain the same quantity of silica; probably that the large pieces floating on the top of the molten mass were somewhat more acid than the lava that lay deeper in the crater and was ejected as powder. The ashes collected by myself at Buitenzorg contained, according to the analysis made at Batavia, 60 per cent; a piece of pumice-stone, collected on the Island Calmeyer, 68 per cent.; a small piece of obsidian from Krakatoa over 68 per cent.; and fine yellow ashes from the east coast of Krakatoa even 70 per cent. of silica. There was found moreover alumina 14 to 16 per cent., protoxide of iron 6 per cent., chalk 4 per cent., soda 4 to 6 per cent., and a little magnesia.

In the microscopic examination of the ashes collected at Buitenzorg there was found—(1) *glass* in innumerable irregular fractured particles, generally completely permeated with vacuoles round or oval; in some particles the glass threads are bent. Those glass particles, microscopic pieces of pumice-stone, are always present in large abundance. (2) *felspar*, very fresh and clear, sometimes with distinct polysynthetic twin lines, generally, however, in single crystals; all seems to be plagioclase, as the analysis shows no potash. As inclusions in the felspar are found glass, apatite, augite, and magnetite. (3) *pyroxene*, partly green and then extinguishing obliquely, therefore monoclinic augite, partly coloured brown, and then, as it appears, extinguishing in parallel lines; it is not yet quite certain whether these last brown augites, which are present in much larger quantities than the green ones, belong to a rhombic pyroxene (bronzite or hypersthene), or are brown monoclinic augites which lie in the preparations on the orthopinacoid. This would be fortuitous; but if the orthopinacoid is much more developed in those crystals than the klinopinacoid, it is not surprising. I also believe I observed in one brown cry[illegible] oblique extinction, while sometimes transitions from brown to green tints occur. Inclusions are glass, apatite, magnetite. (4) *magnetite* in grains and oc-

tahedra, as the oldest component part. The quantity of magnetite decreases in the ashes in proportion as they fell further from Krakatoa.

If the molten mass had slowly cooled, an ordinary augite-andesite or andesite-steatite (with rhombic pyroxene), would have originated.

The thickness of the ejected substances diminishes on the whole as the distance from Krakatoa increases; the coarser material fell principally within a circle, with a radius of 15 kilometres drawn round Krakatoa, although pieces of the size of a fist were still thrown at a distance of 40 kilometres. Within the circle of 15 kilometres' radius the thickness of the layers of volcanic substances is 20 to 40 metres. At the back of the Island of Krakatoa, the thickness of the ash mountains at the base is in some places even 60 to 80 metres, but diminishes in thickness upwards, so that, in the deep clefts, which have already been hollowed out by the water, the old surface of the mountain and the fallen trees appear.

The thick layers of ashes were cooled at the top at the time of my visit, but were still very hot below, so that in the deep ravines hot water and steam appeared everywhere; also at Verlaten Island, Long Island, the Islands Steers and Calmeyer, and even at Sebesi, steam was seen to escape here and there. At Krakatoa there are, besides, stems of trees which have been carbonised by the hot ashes and continue to smoulder close to the fracture, where the air can penetrate, so that at night a little fire-glow and smoke may be observed. These small fires specially gave rise to the report that Krakatoa was still active.

The ascent of the mountain from behind, on the pumice-stone elevations, is difficult, but possible; the innumerable crevices, into which one must constantly descend, make the climbing up in the great heat and the total want of shade very fatiguing. The ascent may be made from the north-west, close along the rupture till about 20 metres from the top, which, according to our measurements, lies 831 metres above the sea; the surroundings of the top are rent and constantly crumbling away.

Between Krakatoa and Sebesi there is a large quantity of ashes and pumice-stone which has filled up that entire part of the sea, and projects in two places above the surface. To these two points the names of Steers Island and Calmeyer Island have been given. They do not rise more than a few metres above the sea, have much to suffer from the beating of the waves as they only consist of loose material, and will soon be washed away. The sixteen small craters between Sebesi and Krakatoa, reduced in later reports to six or four, have never existed. The smoking volcanic accumulations have been mistaken for active craters which, at first, from a distance was not unlikely to happen.

The finer ashes were blown eastward (east-south-east), to near Bandoeng (250 kilometres from Krakatoa), in a north-north-west direction to Singapore and Bancalis, respectively 835 and 915 kilometres from Krakatoa, in a south-west direction as far as Kokos Island (Keeling Island), 1,200 kilometres from Krakatoa; how far the ashes were projected west, north, and south is unknown; the surface comprises at least 750,000 square kilometres, that is, almost as large an area as Sweden and Norway, larger than the Austro-Hungarian Empire, also larger than the German Empire with Denmark (including Iceland), the Netherlands, and Belgium together, and twenty-one times the size of the Netherlands.

Evidently the prevailing wind-currents, *i.e.* south-east and north-east, have carried the particles along, which causes the outline of the surface covered with ashes to be irregularly curved.

Finer particles still have fallen even beyond this line into the sea, as appears from reports of ships; and the finest of all, mixed with a quantity of vapour, remained a long time floating in the upper air-currents, and, propelled by the wind, have made a journey round the world. The vapour was condensed to water, and froze in the cold currents; the refraction through the innumerable ice crystals caused the beautiful dark red glow which was observed the last months in so many places in Asia, Africa, Europe, and America; while the ash particles partly obscured the sunlight, or gave the sun blue and green tints at its rise and setting.

If one considers that the volume of the solid ejected substances already amounts to several cubic kilometres, and that the volume of ejected gas substances was perhaps hundreds of times as large, the hypothesis of a cosmic ice cloud to explain the air phenomena seems to me quite superfluous.

That the ash particles, as a matter of fact, were carried very far in the upper air-currents, has already appeared from snow which fell in Spain, and rain in the Netherlands, in which the same components were found as in the ashes of Krakatoa; and that the particles must moreover have been projected *very* high at the last eruption may be concluded from the report that, on the 20th May, during one of the first eruptions, the steam cloud—according to the measurements taken on board of the German man-of-war, *Elisabeth*, which left Anjer that morning at nine o'clock—must have reached a height of at least 11,000 metres. During the much more violent explosions of August 26 and 27, the height, if the above report may be relied on, may very well have reached 15 to 20 kilometres.

I found that on calculating as accurately as possible the quantity of ejected solid substances, they reached 18 *cubic kilometres*. In doubtful cases the lowest figure was always selected, so that 18 kilometres may be too low, but not too high, a computation. The possible margin amounts in my estimation to not more than 2 or 3 cubic kilometres.

However large a quantity this may be, it does not nearly reach that which the Tombora produced in 1815, and which Junghuhn estimates at 317 cubic kilometres; this computation, however, rests on but few data, so that in my opinion a quantity of 150 to 200 cubic kilometres will come nearer the truth. But even in that case the number is eight to eleven times larger than ours, which is not astonishing, as at that time at Madura, a distance of more than 500 kilometres from the Tombora, the sun was totally obscured *for three days*, whereas the darkness here only lasted *a few hours*.

Of these 18 cubic kilometres, which represent a weight of more than 36×10^{12} kilogrammes, no less than 12 cubic kilometres, or two-thirds of the whole ejected quantity lies within the circle with a radius of 15 kilometres drawn round Krakatoa. As the sea between Krakatoa and Sebesi was not deeper than 36 metres, and the thickness of the volcanic ejections amounts to almost the same, the navigation there has become quite impossible. A little further the thickness diminishes considerably. From 15 to 22½ kilometres from Krakatoa, the average thickness amounts to no more than 1 to 1½ kilometres; within this ring lies Sebesi, which now only presents a heap of ashes, with a few projecting stumps of trees; nothing here remains of the four populated kampoengs which formerly stood on the plain opposite the small island Mengoenang (Huisman's Island), all has been washed away, and is covered with a layer of ashes 1 metre thick. From 22½ to 40 kilometres, the average thickness of the ashes amounts to 0·3 metre, then to 50 kilometres 0·2 metre. At a still greater distance from Krakatoa the thickness speedily diminishes to 2, 1, and half a centimetre, but the finer the ashes become the more the direction of the wind is perceptible. An "ash map" will be added to the detailed report.

One more very remarkable phenomenon during the eruption was the formation of powerful sea waves, which flowed over the low-lying coast districts of the Straits of

Besides, a remarkable fact must be taken into account, namely, that the largest wave, the only one which spread great distances along the north coast of Java and to the south-west, and which surpassed all other waves by far in height, was almost seen nowhere; at Tjiringin alone this wave was seen to approach before the darkness began, and this was about ten o'clock on the morning of the 27th. Anjer was already destroyed at 6 a.m., and then abandoned. At Telok Betong, and in the lighthouses on the Vlakken Hoek, and at Java's First Point, the wave was not seen because it was pitch dark. Even in the lighthouse, 40 metres above the sea on Java's First Point, nothing was seen of the wave, and the destruction of the coast country was only discovered the next morning when it became light.

As the great darkness at Bantam set in soon after the great detonation of 10h. 5m.—the same explosion which gave rise to the great air wave—and as the wave had only time, before the darkness set in, to reach the neighbouring Tjiringin, which lies 47 kilometres from Krakatoa, this tide wave cannot have arisen much before 9h. 50m. or 9h. 55m. At the Vlakken Hoek, 103 kilometres from Krakatoa, it appeared at about 10h. 30m., which agrees with our time computation, if it be taken into account that the velocity of the waves towards the Vlakken Hoek must have been greater on account of the greater depth of the sea than towards Tjiringin.

It is very probable that shortly before ten o'clock a subsidence of the hollow crater walls of one or both of the active craters took place, that through this the water gained access in large quantities, and that then half of the peak, which had been *previously undermined and fractured by the eruptions*, also disappeared in the depths. The cause of the great wave motion must no doubt be sought for in the subsidence of the peak. Of the northern part of the island, after the many eruptions, not much more than a hollow shell can have remained, the subsidence of which could not have caused waves of great importance; nor could the rush of the water produce great waves, but rather a suction towards Krakatoa, and this may be the cause of the water on the coast *first* retreating in various places before the great flood advanced.

The peak itself, however, was still massive, and I have calculated that the part which fell of this mountain alone, without Danan and Perboewatan, possessed a volume of at least 1 cubic kilometre. If this cubic kilometre be suddenly plunged into the sea, the same quantity of water must be displaced, which must give rise to a circular wave round Krakatoa.

There have been, however, other smaller waves; one as early as Sunday evening, August 26, at 5h. or 5h. 30m., two more in the night, and on Monday morning at 6h. a wave which destroyed Anjer. It is difficult to account for the small waves by assuming that parts of the mountain gave way, because, if so, probably the sea would have gained access also, and mud eruptions would have occurred much sooner, unless it be supposed that mud was ejected, but nowhere far enough to reach inhabited places, which is not quite impossible.

according to our measurements as follows:—15 metres up the lighthouse at the Vlakken Hoek; at Beneawang (Semangka), uncertain; at Telok Betong, before the house of the Resident, 22 metres; at the Apenberg (Goenoeng Koenjit), 24 metres; at Kalianda, up a sloping plain, 24 metres; on the south side of Thwart the Way, ± 35 metres (not measured); on the south side of Toppershoedje, 30, on the north side, 24 metres; at Merak itself the height cannot be ascertained with certainty, the old house of the engineer stood only 14 metres above the sea; about 2 kilometres south of Merak, 35 metres; north of Anjer, on the coast opposite Brabandshoedje, 36 metres. The height, therefore, varies everywhere, and depends on the situation of the places, their distance from Krakatoa, their being more or less sheltered, and the steepness of the coast. At Sebesi there is no trace left of the tide wave, as everything is thickly covered with ashes, which fell after the wave. At Seboekoe the height amounts from 25 to 30 metres, but no measurement was taken.

The big wave which was propelled from Krakatoa at about 9h. 50m. spread over great distances, among others as far as Ceylon, Aden, Mauritius, Port Elizabeth in South Africa, and even to the coast of France. The velocity of the waves varies greatly, of course, since it increases with the depth of the sea; I shall not be able to give a detailed summary till the tables of all the self-registering tide apparatus shall have been collected. For the Indian Archipelago, and a few points beyond, I found the following numbers:—

Places	Velocity per hour in miles	Average depth of the sea in metres
Island Noordwachter	37 ...	37
Tandjong-Priok (Batavia)	36 ...	35
Undeepwater Island	33 ...	29
Dendang (Billiton)	31 ...	26
Tandjong-Pandan (Billiton)	32 ...	27½
Tjilamaja (Krawang)	31 ...	26
Oedjoeng Pangka (near Soerabaja) ...	29¼ ...	23
Pasar Manna (Benkoelen)	113 ...	344½
Padang	109 ...	320¼
Mauritius (Port Louis)...	(364)? ...	(3575)?
Port Elizabeth	306 ...	2526

In our Archipelago the velocity is small, owing to the shallowness of the sea, but in the deep sea, on the route to Mauritius and the Cape, it increases considerably, *i.e.* amounts to more than 300 knots an hour, a velocity which is alone to be compared to that of the lunar tide wave and the earthquake waves of Simoda, in Japan, of December 23, 1854, and of Tacna, in Peru, of August 13, 1868.

From the velocity of the wave the average depth of the sea between the places along its path can be determined; I have put together in the foregoing table those various degrees of velocity, but they can only be trusted when the height of the wave is small with respect to the depth of the sea, which in our Archipelago is not strictly the case. However the numbers agree pretty well with the sea-chart. In the time computation of Mauritius there appears to be a mistake, as the average depth cannot be so different from that of Port Elizabeth.

After these terrible events Krakatoa slowly calmed

down, not however without having still violently roared in the evening and night of August 27 to 28. The detonations were scarcely less strong at Buitenzorg from ten to one o'clock than in the morning. But after the 28th nothing more was heard of the mountain. The tidal registrations at Tandjong Priok exhibit still a few small oscillations till August 30 at twelve o'clock in the day, but after that the condition of the water also became normal. Notwithstanding this I found that there must have been a serious eruption a considerable time after August 28, and shortly before I visited the island.

On October 11 I left Batavia with my staff, and after having visited various points in the Straits of Sunda, arrived at Calmeyer on the 15th. We stopped a few hours in order to survey the island, which is a perfectly bare bank of pumice-stone, divided into seven parts by encroachments of the sea; the temperature was 42° Celsius, a heat which almost stupefied us. Here already my attention was drawn to the fact that the white or pale gray pumice-sand was covered by a 0·2 metre thick layer of darker coloured very fine ash, which exhibited numerous fissures on the surface, produced in the process of drying, and therefore had probably fallen there as wet mud. I did not, however, then attach any special importance to this phenomenon.

On the 16th I arrived at Krakatoa and remained there till the 18th. When in surveying the mountain on the 17th we had climbed to the top, and began the steep descent on the south side, I observed with astonishment that on the ordinary gray pumice-stone material two black streaks were visible, which began 600 metres above the sea, therefore about 200 metres lower than the top, and could be traced in a tolerably straight line over a length of 1300 metres till 100 metres above the sea. These black streaks proved to be two mud streams, which had flowed down the slope of the mountain and had covered the white pumice-stone to the thickness on an average of 0·2 to 0·3 metre and a breadth of 1 to 5 metres. The most remarkable fact was, however, that these mud streams were not only traced down the back of the mountain but had also flowed into the deep ravines of pumice-stone material, as can be distinctly seen. Therefore those mud streams did not arrive there till the crevices in the pumice-sand already existed, and as several weeks must have been required for the water to hollow out these ravines the mud eruption cannot immediately have followed the eruptions of August. The very fine dark gray mud was still damp at the time of my visit, and could be kneaded with the hand, which also proves that the streams were of recent origin.

In this eruption very curious objects were ejected, *i.e.* very smooth, round balls resembling marbles, to the size of 1½ to 6 centimetres in diameter. They are full of acids, they contain 55 per cent. carbonate of lime, 26 per cent. silica, 11 per cent. alumina, and 5 per cent. water. These calcareous lumps of marl must be derived from layers of marl which exist at the bottom of the Straits of Sunda in the neighbourhood of Krakatoa, and the slime or dust of which has been shot out of the crater in a rapid revolving motion. The balls, which are rare, are never found inside but only on the top of the pumice-stone dust, generally half sunk in the sand; they evidently belong to the last ejections. Whether the mud streams also contain lime I have not been able to ascertain, as a piece brought as a sample has unfortunately been lost.

The last mud eruption, which must have been very important, since on Calmeyer, 12 kilometres from Krakatoa, the upper black layer is 0·2 metre thick, and the mud must have been thrown over the top, which is 830 metres high, to the back of the mountain, whence it poured down, probably took place only six days before my arrival, namely on October 10, at about 9h. 30m. in the evening, because on that evening at about ten o'clock a considerable tide wave arrived at Tjikawoeng in Welkomstbaai (Welcome Bay), the only tide wave which was observed since August 28. A rumbling sound in the direction of Krakatoa was then heard in that place, as well as a little more northward at Soemoer. The wave overflowed the shore to a distance of 75 metres beyond the tide-mark at Tjikawoeng, but has not been observed at other points of the coast, as the devastated coast country was not yet inhabited and was quite abandoned at night. We find in this another proof that the falling down of large quantities of ejected substances round Krakatoa suffices to form important waves in the Straits of Sunda.

The eruption on October 10 seems to have been the last. But this eruption was scarcely noticed, and it is therefore possible that subsequent feebler volcanic actions may have remained quite unobserved. When I visited Krakatoa there was nowhere any sign of activity. On October 18 we left Krakatoa, and we arrived on the evening of the 19th at Vlakken Hoek, where nothing was noticeable. It is not likely, therefore, that the rumbling sounds which were heard that evening at Tangerang and Mauk coming from the west should have proceeded from Krakatoa. It would, however, be very interesting to visit Krakatoa once more in order to be able to trace whether any more changes have taken place since October 18.

Though there is no fear of any serious eruption of Krakatoa after the terrific activity of the volcano and the subsidence of the greater part of the island, still much that is interesting may be learnt yet from less important subsequent volcanic actions, as we see in the instance of the lumps of marl.

With the detailed report a large map of Krakatoa will appear, as well as maps of Calmeyer, the devastated parts of Merak, Java's First Point, Sebesi, Seboekoe, Telok Betong, and Kalianda; moreover tables indicating the pressure at the gas-works at Batavia, and of the self-registering tidal apparatus at Tandjong Priok and at Soerabaja; a small "ash map" and other supplements, and finally a few coloured drawings of Krakatoa and the devastated districts, where in a few moments tens of thousands of people lost their lives on the memorable 27th of August, 1883. R. D. M. VERBEEK

Buitenzorg, February 19, 1884

THE LATE MONSIEUR DUMAS

AT the funeral of this eminent chemist addresses were given by the representatives of various official bodies. From these we subjoin the following extracts, affording as they do an idea of the estimation in which M. Dumas was held by his contemporaries, and of the position to which he is entitled in the science of the present century.

M. le Comte d'Haussonville, Director of the French Academy, said:—

"Who was more worthy than Jean Baptiste Dumas of the high distinctions conferred on him by the Academy of Sciences! By us he was welcomed at a time when his name already ranked amongst the most illustrious of our times, when he had already been hailed as a master by associates destined soon to become masters in their turn. To their authoritative voice, rather than to me, must belong the duty of recording the signal services rendered to science by our regretted colleague, whose mortal remains lie at our feet. They will tell you with a fulness far beyond my power how, under the first inspiration of his soul, he understood how to vary his experiments and verify his assumptions. And with what supreme delight, says one of our *confrères*, who had the honour to receive him into the Academy, he pierced with eagle-eye into the depths of the divine laboratory, beyond which there is naught but the infinite, the unfathomable, the unapproachable! Speaking of his own work, he himself thus expresses himself:—'Above the sphere of phenomena which we study, and where such a vast field of discovery still

lies open before us, there is still a higher sphere inaccessible to our methods. We begin to understand the life of bodies; that of the soul belongs to another order.' My years, near enough to those of the venerable seer by whose death we are overwhelmed with grief, enabled me to assist at one of M. Dumas' earliest triumphs. It was before the year 1848, when in his official capacity he ascended the tribune of the House of Deputies in order to expound the whole mechanism of minting in connection with a law then under discussion. Notwithstanding the dryness of the subject, I still remember how we remained for two hours captivated by the charm of his natural eloquence. In taking leave of so great a memory, permit me to repeat the glowing words recently uttered by M. Dumas himself on the occasion of the death of his distinguished colleague, M. Regnault: 'The Academy, faithful interpreter of posterity and sole heir of your renown, hastens to render a public homage of affection to your person, of thanks for the great and noble work of your life, of respect for your brilliant services, awaiting the time when science and your country shall pay their debt to a name worthy of every honour.'"

M. J. Bertrand, Perpetual Secretary of the Academy of Sciences, said:—

"M. Dumas has been our universal teacher. His lectures at the Athenæum, at the College of France, at the Central School, at the School of Medicine, the Faculty of Sciences, and Polytechnic, had so many attractions, he understood so well how to inspire his audience, he indicated the path of progress so clearly, and made each discourse so finished and perfect in itself, that all alike withwithdrew resolved not to miss the following lecture.

"In the history of reformed chemistry no name will assuredly eclipse that of M. Dumas. Eager to disseminate his ideas, skilful in placing his proofs in a clear light, his wise and lofty intellect surveyed from a high standpoint the main routes of science, acting ever as a faithful guide to all who, younger than himself, considered that they honoured themselves in proclaiming him their master."

M. Rolland, as President of the Academy of Sciences, naturally entered into some detail on the scientific work of M. Dumas. Among other things he said:—

"The scientific work of J. B. Dumas is immense, and his labours have long shed a lustre on his name. In his thirty-second year he had already joined the Academy of Sciences, of which he subsequently became one of the most eminent and respected members. I cannot attempt here to mention all the numerous discoveries due to his genius, by which he has so potently contributed to the establishment of modern chemistry, herein showing himself the worthy successor of Lavoisier.

"I will therefore restrict my remarks to the second period of his career, during which, as Perpetual Secretary of the Academy of Sciences, he enabled us better to appreciate his subtle and lofty intellect, his profound knowledge of men and things. Hence his authority was unanimously recognised by his colleagues, whose councils and labours were so often controlled by him with admirable tact and prudence under peculiarly delicate circumstances. If to these rare gifts be added a fluent speech, a kindly and sympathetic feeling from which he never departed, it will be understood how highly prized was the combination of these exceptional qualities, how valued by the Academy, where Dumas so often played the part of guide and director.

"These eminent virtues had long been esteemed and utilised by other societies also, such as those of the Central School, of the Friends of Science, and others, over whose labours he had presided for many years. He was also intrusted with the presidency of several international Commissions, where were discussed many important questions in connection with a uniform system of weights, measures, and currency, as well as with the determination of electric units. There might perhaps be reason rather to regret the manifold occupations and public duties which absorbed so much of his time, diverting him from the prosecution of purely scientific researches, where so much might still be hoped from such a powerful genius. For, in spite of a long life devoted to incessant work, our *confrère* had to the last preserved his strong intellect and mental activity.

"But however great and varied were the labours constantly claiming his attention, he never neglected his more personal duties. His was the life of a true patriarch, ever encircled by his children and children's children, who cherished his fair name and ever rejoiced in the constant solicitude of a tender and devoted father.

"Dumas had married the daughter of Alexander Brongniart in the year 1825. All who, like myself, had the privilege to be welcomed in that happy circle, can testify to the intimate and devoted character of their union down to these last days. I may here be permitted to express to the bereaved widow our warmest sympathy in the loss which to-day deprives her of the affectionate support of such a well-beloved husband.

"But the time has come to bid a last farewell to the mortal spoils of our illustrious colleague, whose memory shall ever remain engraved on our hearts, whose name is eternally enrolled amongst those of the great thinkers by whom the nineteenth century has been most honoured."

Following M. Rolland came M. Wurtz, who spoke on behalf of the Faculties of Science and Medicine.

"To those already deposed on the remains of M. Dumas, the University," M. Wurtz said, "adds other wreaths in supreme homage to the teacher by whom we have all profited, to the *savant* who has shed a lustre on our times, to the worthy citizen who has left a void in the hearts of all. Ours is a public mourning, and above the voices which we hear around us I seem to hear the great voice of France, which in Dumas suffers an irreparable loss. For a period of sixty years he served her with distinction under the most varied circumstances.

"To a piercing genius, an intuition leading to great discoveries and broad views of the universe, Dumas added the choicest gifts of eloquence, of a clear and graceful style, gifts which make the orator and the writer. He was the ideal of a French *savant*, and history will award him a place not far removed from that of his admired master, Lavoisier.

"Born at Alais in 1800, he began life as a chemist's assistant in Geneva. But he was scarcely twenty years of age when, jointly with Prévost, he published some researches on various physiological subjects, and notably some experiments on the blood, which have held their ground to the present time. After his arrival in Paris in 1821 he devoted himself exclusively to chemistry, and soon felt himself competent to undertake such grave work as the independent development of organic chemistry, and the reform of mineral chemistry. And if during the last fifty years chemistry has broken new ground, and become, so to say, transformed under our eyes, this has been accomplished in virtue of a programme he was the first to trace, and the foundations of which were laid by his own discoveries. The ideas at that time current had been drawn from the relatively simple study of mineral compounds. All combinations, it was assumed, are formed of two direct elements, themselves either simple bodies or compounds in the first degree. This so-called 'dualism' in chemistry, traceable to Lavoisier, had been adopted and developed by Berzelius, but was overthrown by Dumas. Studying in 1834 the action of chlorine on organic compounds, he detected in this simple body 'the remarkable power of replacing hydrogen atom by atom.' Such was the first announcement of a law which, supported by thousands of analogous cases, now forms the point of departure for the theory of substitutions and its consequences, associated with the name of Dumas. This

conception was developed in a series of memoirs dealing with chemical types, and was later on generalised and simplified by Charles Gerhardt.

"Dumas' studies embraced every branch of the science—discovery and description of mineral and organic compounds, analysis of numerous substances and improvement of the methods of analysis themselves, determination of atomic weights. With the penetration of inventive genius he introduced into all his researches that firm grasp of the subject, that accuracy in details, that critical spirit which are the essential conditions and necessary instruments of all scientific investigation.

"And how shall I speak of his theoretical views expressed on a great variety of special subjects, and embodied either in his great 'Traité de Chimie Appliquée aux Arts,' or in his admirable 'Leçons de Philosophie Chimique'? Merely to mention one point, to Dumas we are indebted for a first attempt at a classification of simple non-metallic bodies, an attempt which has still its value.

"Let me also remind you that, after enriching physiological chemistry at the outset of his career, he soon after endowed physics with a new method for determining the densities of vapour, in continuation of the work begun by his master, Gay-Lussac.

"But a complete idea of his influence and authority cannot be had without reference to his career as a teacher. On his arrival in Paris he opens a course of lectures at the Athenæum. Later on he founds, jointly with Lavallée, Ollivier, and Péclet, the Central School of Arts and Manufactures, where he conducts the chemical class for a quarter of a century. In 1832 he replaces Thenard at the Polytechnic, and the same year is appointed Assistant Professor to the Faculty of Sciences. In 1841 he becomes at once Titulary and Dean of the same Faculty, having three years previously obtained the Chair of Organic Chemistry in the Faculty of Medicine. It was here perhaps that his talents as a teacher achieved their greatest triumphs. He was at that time at the most brilliant period of his creative genius, and he set forth the great ideas then animating him with sympathetic warmth and persuasion, with inimitable clearness and wealth of illustration.

"Such, in a few words, has been the preponderating part played by M. Dumas in science and instruction. And although during his last years he withdrew from public life, it was only to devote himself to work of another order. He was equal to every undertaking imposed on him, the soul of the many committees over which he presided, the ornament of the Academic celebrations which he honoured by his presence and addresses. And after such a long and glorious life what remained except a peaceful end in the midst of his family circle, and in the full enjoyment of all his faculties? But such a commanding figure cannot pass into forgetfulness. Your memory, Dumas, shall be perpetuated, your name transmitted from age to age. You shall live in your works, in the example you have given, in the immortal productions and rare qualities of your mind: *Forma mentis æterna*."

THE EARTHQUAKE

EARTHQUAKES are so rarely observed in England, that an exceptional interest attaches to that of April 22, an interest far in excess of that due to its intrinsic importance. Fortunately the earthquake is exceptional in another sense. It is seldom that a shock results in so small a loss of human life in proportion to the damage done to houses.

The daily London press, for a few days after the occurrence, gave much information as to the range of the earthquake, and the nature and amount of the damage done; further details are given in the local papers of the Eastern Counties, but we are still sadly in want of definite statements upon many matters of great importance. In this article we shall notice only a few points of interest, reserving for a later issue, it is hoped by the aid of fuller knowledge, a more complete account of the phenomena, to be illustrated by a map showing the area of disturbance.

The shock was most severely felt near the north shore of the estuary of the Blackwater, and for about six miles inland to the north, in the direction of Colchester. The geology of this district is simple. Nearly all the country is occupied by London Clay; over the marshy land of the Colne, and the flats separating Mersea Island from the mainland, there is a covering of recent alluvial deposits; over parts of the higher land of Mersea Island there are patches, from a quarter of a square mile to one square mile in area, of Glacial gravel, the remnants of a great sheet of similar material which once overspread the London Clay and joined the large area of similar gravel near Colchester. This town is mostly built on gravel, which rises to a greater height, and occurs in considerable thickness, to the south-west of the town—over Lexden and Stanway Heaths; further to the west and south-west this gravel passes under Boulder Clay. Underlying the whole of the Tertiary beds of the east of England there is a continuous bed of Chalk, from 600 to 1000 or more feet in thickness. Below the Chalk there is a bed of Gault Clay of varying thickness. But here our certain knowledge of the geological structure of the country ends. Rocks of Silurian, Devonian, or Carboniferous age have been proved at various points under the east of England—at Harwich, Ware, Turnford, Tottenham Court Road; rocks of probably Triassic age have been found at Crossness and Richmond. Still further west and north-west the older rocks have been proved at Burford and Northampton. Over Central England the Jurassic and Triassic rocks cover a wide area, but from beneath these the older rocks appear in numerous places.

One of the most interesting questions connected with the recent earthquake is to ascertain whether there be any relation between the known range of these older rocks and the range of the earthquake over areas far distant from its central spot. At first it seemed certain that such was the case. The shock was plainly felt at Bristol, Wolverhampton, Birmingham, and Leicester—all places on or near to the outcrop of the older rocks. Numerous intermediate localities have since been mentioned, many not being connected, so far as we yet know, with the near existence of older rocks; but the far distant places still make it probable that some such connection exists.

It seems therefore likely that the wider and more general range of the earthquake is connected with the range of the Palæozoic rocks, whereas the local phenomena depend very largely upon the nature and thickness of the Secondary and Tertiary rocks. It is therefore important that those who study in detail the effects of the earthquake on the spot should do so with the aid of the Geological Survey Map of the district, which was surveyed by Mr. W. H. Dalton. The map and explanatory memoir are both published; in them the nature of the drift deposits are fully explained.

Almost all earthquakes have a very striking effect on springs and wells, sometimes causing a permanent change, at other times having merely a temporary influence. It is somewhat remarkable that so little has been recorded upon this point. A strong spring at West Mersea, which issues at the base of the Glacial gravel, where this bed rests upon London Clay, is said to have ceased to flow for a short time, and to have been discoloured when the water returned. Any residents in the district who have the opportunity of inquiring into similar cases, which doubtless occurred, will do good service by noting the facts.

Dr. J. E. Taylor's letter, which appears elsewhere, contains much valuable information, such as might well be collected from neighbouring areas; his observations as to the twisting of chimneys, &c., and as to the direction in which that twist occurred, is a case in point.

Information is also wanted as to the angle at which the shock emerged from the ground at various points around the central area, in order that the depth from the surface at which the shock originated may be known. There should be no difficulty in collecting data for this in a district where so many buildings are cracked and shattered. The direction of the cracks, and the angles which these cracks make with a horizontal line, should be carefully noted.

Another point upon which much uncertainty at present exists is the direction in which the wave travelled from its point of origin. The swinging of chandeliers, the swinging of pictures on certain walls and not on others, pendulums which stopped or not according to the direction of the swing, are all important helps towards deciding this question. Of course it is always dangerous to seek for knowledge of this kind some time after the event, but in many cases it may be possible to speak with absolute certainty of the facts.

Some observers speak decidedly of two distinct shocks; this probably was the case frequently, though seldom noticed. The rumbling sound so frequently accompanying earthquake shocks was in many cases noticed in Suffolk and Essex. It is rarely mentioned elsewhere, but is said to have been heard at Chelsea, Reading, and Bristol.

As regards the actual area affected by the shock, there is perhaps much yet to learn. It is recorded along the south side of the Thames from Herne Bay to London, and again at Reading. It was felt at Maidstone and Croydon, and again along the south-east coast from Hastings to Portsmouth and Ryde. But at present we know of no observations in the central parts of Kent, Surrey, or Sussex. W. TOPLEY

WE have received the following further communications in reference to the earthquake:—

As all facts connected with the earthquake shock on Tuesday may prove of more or less value, I beg to communicate the following. The house which I occupy is situated in the centre block of buildings constituting Inverness Terrace, on the western side. Under this block of houses runs the Underground Railway, but a distance of one hundred paces from my house. During the daytime the passage of trains is wholly unperceived, but during the night, when heavy luggage-trains run, a very perceptible vibration is experienced, and in the stillness a distinct rumbling is heard. On the morning of Tuesday I was engaged reading, when my attention was called to what I supposed to be the passage of a train; but the peculiarity of the motion speedily undeceived me. The sensation was that of being borne rather on water than on solid earth, and as I had already had experience of an earthquake shock in India, I suspected that this disturbance I was feeling was of the same nature. I immediately looked at my watch and noted the time as being thirty-two minutes past nine o'clock. As no one of the other three inmates of the house had perceived anything unusual, I thought no more about the matter until I saw the announcement in the evening papers of what had happened. I then went to the watchmaker's and found that my watch was just fifteen minutes too fast. I am therefore able, with fair approximation to accuracy, to fix seventeen minutes past nine o'clock as the time at which the vibration ceased at this point. W. C. B. EATWELL

69, Inverness Terrace, Kensington Gardens, W., April 24

ON Wednesday morning last, the day after the earthquake, I determined to start upon its track. In Ipswich here, little or no visible harm has been done; but no sooner had I arrived at Colchester and commenced to walk through the town, from the chief station to the Hythe, than abundant evidence of the ruin wrought by it was visible. Chimneys were totally thrown down, and the brickwork had crashed through the frail roofs. Others were standing, but they looked as if they had been struck by lightning. Their upper parts were splintered and laterally expanded. I could not help noticing that nearly all the houses whose chimneys were wrecked were the oldest—hardly any of the modern, cheaply-built cottages being affected, contrary to my expectation.

At Wivenhoe I found the appearance of the town best expressed by the remark already made: "It looked as if it had been bombarded." That was the first idea which rose in my mind.

Hardly a house was untouched, inside or out. The *newest* houses seemed to be externally least affected, but they made up for this inside. They looked as if they had been given a few half turns, and then shaken up. The plaster had been detached from all the walls, the roofs were rent and loosened all along the cornices, and the framework of the windows was everywhere splintered or free. The battlements of the grand old church had been thrown down, and about fifteen tons of rubbish lay among the crushed headstones and the delicate and abundant grave flowers. Here again there was evidence of a semi-rotatory motion on the part of the earthquake. The beautiful Independent Chapel is so utterly wrecked within and without that it will all have to come down. The streets were full of bricks, mortar, and tiles, although with characteristic English tidiness and diligence the terror-stricken inhabitants were already clearing away the debris. I noticed several houses with rents at the bases of their walls, and in such of the chimneys as remained standing they were frequent. One thing struck me, the rents sprang at an angle of about 30° at the bases of the buildings, whilst in the chimneys this was increased to from 40° to 45°.

The old ferryman related his experience after the manner of an old salt. He was just bringing his boat to the shore when the shock occurred—"it seemed just like *three seas*," he said—a capital and vivid expression to convey an idea of the wave-motion.

Crossing the river I made my way through Fingrinhoe village, and on to Langenhoe. I did not see a single house on the road, large or small, for a distance of about four miles, that had escaped untouched. The fine old Jacobean hall at Fingrinhoe has lost the upper part of the western side of the front elevation. Here I found some of the chimneys that had been left standing *twisted* on their pediments. I carefully noted this on the way, and on examining those of the massive chimneys of the rectory at Langenhoe, the torsion was very plainly visible. The twist had come from the south, for the faces of the chimneys which had previously looked in that direction were now turned almost south-easterly. I did not set out a minute too soon to note these circumstances, for all the builders of the countryside were already abroad, and in a few days all the evidences of earthquake action of the greatest value to seismologists will have been completely obliterated. Thus I found a very intelligent builder from Colchester on the lawn of the Langenhoe Rectory, giving orders for having the twisted chimneys removed, and I have no doubt they were all taken down within twenty-four hours. He had been driving all over the disturbed countryside, and told me that wherever the big chimneys had been left they were twisted from the south-south-west to the north-north-east, especially in the contiguous villages of Peldon and Abberton. This, I think, settles the original direction of the earthquake wave, and also establishes its rotatory character.

Langenhoe Church is an utter ruin, and all that yet stands will have to come down. It is a sad sight to see this picturesque, ivy-clad old church—standing so prettily overlooking the creeks where the ancient Danish Vikings landed in the dawn of our modern history but a comparatively few years before the church was built—now so utterly ruined. The porch on the north side is of brick, and a modern structure. Two large rents run up, one on each side of the doorway, at an angle of about 32°. They run from opposite directions, and meet just above the keystone of the arch. Here another large rent parallel with the ground traverses the masonry. It seemed to me that the first earthquake shock which rent the brickwork sprang from the western corner, and was reflected so as to form the opposite rent, after striking and lifting up and forming the parallel crack above-mentioned.

The battlements of Langenhoe Church, like those of Wivenhoe, have been shaken down. But while those of Wivenhoe were thrown upon the ground chiefly on the *west* side, those of Langenhoe Church were thrown on the nave—that is, in an opposite or *easterly* direction. They crashed through the roof and carried a gallery with them, the concussion meantime bursting out the upper part of the chancel end. Am I right in thinking that this pitching forward of the loosened rubbish in opposite directions, as exemplified in these two churches, taken in connection with the overwhelming proof of rotatory motion, indicates that the movement of the earthquake had swerved right round be-

tween Wivenhoe and Langenhoe? In that case does it not also suggest the *local* character of the earthquake?

Langenhoe and the adjacent villages, with the Isle of Mersea close by and in full view, appear to form the focus of the disturbance. So far as I have been able to learn, the clocks stopped by the shock were those facing the north.

I see the newspapers refer to various cracks and fissures in the ground at Langenhoe, Abberton, Mersea, and elsewhere, as having been caused by the earthquake. I saw numbers of them, but in every instance they were the ordinary cracks which always appear in the London Clay during a drought, or after a spell of dry weather like that of the last three weeks. In none of the instances I saw had the fissures anything to do with the earthquake.

The local character of the area of chief disturbance is not only indicated by the different directions in which the rubbish was thrown from the battlements of Wivenhoe and Langenhoe Churches relatively, but also by the fact that whilst the western side of Mersea Island suffered severely, the eastern side was only slightly affected in comparison.

Museum, Ipswich, April 26 J. E. TAYLOR

THE earthquake was felt here very plainly, and I am able to give some evidence as to the amount of oscillation experienced at the moment when the wave passed under Cambridge. I happened to be looking at my marine aquaria at rather more than twenty minutes past nine on Tuesday morning (I regret I did not notice the *exact* time, but that was about it), and the water in them distinctly moved. The oscillation was not violent, as if produced by a concussion in the air, such as an explosion would cause, but rather as if the table on which the aquaria stand had been tilted up to the extent of an inch, and in the direction of a line running east and west. I was looking more particularly at a very shallow aquarium in which I keep shrimps, mussels, and sand-loving annelids, and one portion of which has less than a quarter of an inch depth of water. This was tilted up so much that the sand at the shallow end was quite uncovered by the water, and my first thought was that evaporation had taken place during the preceding night to such an extent as to endanger the lives of the nereids and other creatures; I therefore went hastily for some fresh water, but upon returning with it in a minute I found the water at its normal level, and I had no necessity to pour any fresh in. I remember, too, that I was sensible of a slight giddiness at the time, and the house and everything in it seemed to be moving. The sensation indeed was much like being on shipboard. I had no suspicion of the real cause, but thought it was a slight faintness, as I had not then breakfasted.

Mill Road, Cambridge, April 23 ALBERT H. WATERS

THE following memoranda may be of interest:—On January 8, 1869, I was with Prof. Dawkins, engaged in examining the late Mr. Whincopp's collection at Woodbridge, Suffolk. On my way home I was delayed three hours at Bury St. Edmund's in consequence of a luggage-train having broken down to the eastward. While there I was told that an earthquake had been felt that day at Thurston, Elmswell, and Haughley, places between Ipswich and Bury. It was reported that a workman, sitting eating his luncheon on the bank, saw the rails move. Mentioning this when I returned home, I was told that the policeman in this village had felt a shock. I therefore interviewed him and made the following note:—"January 15, 1869: P.C. Redhouse, when near the 'Hare and Hounds'" (which is a few hundred yards south of my house) "on Sunday morning the 3rd, about 2 a.m., heard a sound like heavy distant guns, which seemed to shake him and to make him reel. He was walking fast, and stopped. There was no shake after the sound. He thought there were six or seven reports in a couple of seconds. The movement was from north to south. There were three sounds before he stopped, and three afterwards. He did not regain his steadiness for two or three chains' distance. The sounds were very heavy, and he went home in alarm." I was awakened the same night by a tremor of the bed. This occurred a week before the shock in Suffolk. The late earthquake was preceded at Langenhoe by a slighter one on February 18.

A yacht captain at Wivenhoe happened, on the 22nd inst., to witness the effects from the top of a ladder. Hearing a rumbling sound, he looked about him and saw the church and all the houses rocking about, some one way and some another, "like a lot of pleasure-boats at the seaside with a gentle swell on." This seems to show that the length of the wave could not have been great, but that it must have been in opposite places withi a few hundred yards. Knowing the district well, it strikes me as remarkable that the strength of the shock should have been so much localised, while the distance over which it was slightly felt was so extended. O. FISHER

Harlton, Cambridge, April 28

ALTHOUGH this Observatory does not possess a seismograph, yet the passage of yesterday's earthquake wave was recorded by the magnetographs, although I am not aware the shock was felt by any one in this neighbourhood. It was registered at 9.17-18 a.m. G.M.T., and from the fact that the disturbance of the horizontal force magnetometer was the greatest, we infer that the terrestrial movement was rather north and south than east and west. G. M. WHIPPLE

Kew Observatory, Richmond, Surrey, April 23

PROBABLY one of the extreme limits of the action of the earthquake of April 22 was at Street, Somerset, ten miles beyond the Mendip main anticline. There it was *certainly* felt by an invalid lady, who mentioned it at midday dinner, only a few hours after, no news having been received, of course, from other parts. Has there been any certain record of it north of the concealed Palæozoic ridge across the North Midland counties?

York, April 28 J. EDMUND CLARK

NOTES

AT the meeting of the Executive Committee of the City and Guilds of London Institute held on Tuesday, the following appointments were made at the Central Institution, Exhibition Road:—To the Professorship of Chemistry, Henry Armstrong, Ph.D., F.R.S., of the Technical College, Finsbury; to the Professorship of Engineering, W. C. Unwin, D.Sc., of the Royal Engineering College, Cooper's Hill; to the Professorship of Mechanics and Mathematics, Olaus Henrici, Ph.D., F.R.S., of University College, London; to the Professorship of Physics, Oliver Lodge, D.Sc., of University College, Liverpool.

IN a crowded house on Tuesday last the Convocation of the University of Oxford passed the much-debated statute allowing women to enter for "certain of the honour examinations of the University." The statute has been opposed on very different grounds. The old Conservative Oxford School (fast becoming extinct among the resident teachers) of course objected to any change in favour of the higher education of women; with them went a portion of the High Church party, who look with disfavour on any proposal tending to bring women into intellectual competition with men. Others, again, opposed the statute on the ground that it was unfair to men, who have to keep certain terms and pass certain examinations within a specified time if they wish to enter for an honour school, whereas the statute allows women to enter for honours without the same preliminary examinations, and without restrictions as to time and residence. Others again feared an influx of young ladies into Oxford, as likely to destroy the manliness of the undergraduates and spoil the natural modesty of the lady students. To these arguments the success which the present halls for ladies in Oxford have met with is the best answer. Their presence has not revolutionised the University; they have not been a stumbling-block to discipline nor a rock of offence to the Church. The women's examinations, conducted by the delegates, were exactly on the same subjects, and the papers were set by the same men, as in the men's honour examinations *before this* statute passed. Now the same papers will serve for both, trouble will be saved, and the women who obtain honours will win a certificate universally recognised throughout the country. Oxford is to be congratulated on Tuesday's vote.

THE Rede Lecture at Cambridge University will be delivered on May 28 by Mr. Francis Galton, the subject of the lecture being "The Measurement of Human Faculty."

We are informed that tickets have been applied for as follows for the Montreal meeting of the British Association:—Members elected prior to October 1882, 379; Members elected since October 1882, 181; Associates (relations of Members), 120; total, 680.

The International Geological Congress will hold its meeting in Berlin this year, towards the end of September.

The International Polar Conference concluded its labours last Thursday.

In reference to the recent sunsets a correspondent writes that Graham's Island was in eruption, throwing out vast quantities of steam, ashes, and cinders from July 19 to August 16, 1831, and in connection therewith sends us the following extract from a letter written from Malta, January 28, 1832 (see *Phil. Trans.* 1832):—"In the month of August a singular appearance was witnessed in the heavens, many evenings successively, both here and in Sicily. Soon after sunset the western sky became of a dark, lurid red, which extended almost to the zenith, and continued gradually diminishing in extent and intensity even beyond the limit of twilight. This phenomenon, too, was attributed to the volcano, and was supposed by many people, whom it greatly alarmed, to be portentous of some impending calamity." Our correspondent also sends us the following old translation of Virgil's "Georgics," Book i. line 542:—

"He, too, bewailing her unhappy doom
When fell her glorious Cæsar, pitied Rome,
With dusky redness veiled his cheerful light,
And impious mortals feared eternal night;
Then, too, the trembling earth and seas that raged,
And dogs and boding birds dire ill presaged;
What globes of flame hath thundering Etna thrown,
What heaps of sulphur mixed with molten stone,
From her burst entrails did she oft expire,
And deluge the Cyclopean fields with fire."

The Kew Committee of the Royal Society have affiliated to the Department for the examination and verification of scientific instruments a branch which will rate watches for either makers or the public on very moderate terms.

The Council of the Royal Geographical Society have decided to appoint for one year an inspector, to inquire thoroughly into and report on the state of geographical education at home and on the Continent. In addition to studying the best methods of geographical teaching—chiefly probably in Germany and Switzerland—he will be required to collect and report on the best text-books, maps, models, and appliances. His honorarium will be 250*l.*, to include travelling expenses, but not the purchase of books, &c., which will be defrayed by the Society on the selection being approved by the Council.

Science in Japan has recently suffered a severe loss by the death of Dr. A. J. C. Geerts, which took place at Yokohama towards the end of last year at the early age of forty. He had been for fifteen years in the employment of the Japanese Government, and a few weeks before his death his services had been recognised by the Emperor, who conferred on him the Order of the Rising Sun. Dr. Geerts was originally Professor of Chemistry in the School of Military Medicine at Utrecht, and in 1868 was offered by the Japanese Government the post of Professor of Natural Science at the Medical School then recently established at Nagasaki. After occupying this position for five years he was nominated adviser to the Department of Hygiene and Public Health in Tokio, and was also charged with the establishment of a chemical laboratory at Kiôtô. In 1877 he established a similar institution in Yokohama, where his duties consisted chiefly in the testing of foreign drugs imported for sale amongst the Japanese, and this position he held at the time of his death. Like every other European in the Japanese Government service whose duty compels him to stand between his own countrymen and the natives, and to hold an even balance between the claims of both, his work was frequently of a harassing and unpleasant description; nevertheless he found time to write numerous works on Japan. His papers on Japanese mineral products, communicated during a number of years to the two learned societies in Japan, are of much value. He also published a Japanese Pharmacopœia, an account of the numerous mineral springs in Japan, and finally he commenced, and actually published, two volumes of an encyclopædic work entitled "Produits de la Nature Japonaise et Chinoise," in which he intended to describe the names, history, and application "to arts, industry, economy, medicine, &c., of substances derived from the three kingdoms of nature, and which are employed by the Japanese and Chinese." The formidable nature of this title is in no degree diminished when we come to examine the torso of the work itself. Ordinary men, who bear in mind that human life and human powers are limited, can only stand amazed at the conception of this work; for the author not only ransacked all that had ever been written on China and Japan in Europe, but also examined the whole of Chinese and Japanese literature before he sat down to write even the most insignificant article. In the section "Iron" alone one finds about 200 references to works in all literatures and of all ages. Each section contains the Japanese and Chinese legends respect- in the origin and discovery of the production which formed its subject, the places where it has been or is now found, the primitive modes of obtaining it, the various qualities ascribed to it, its employment in arts and industry, &c. From this method of writing, it was inevitable that the work should bear the appearance of a hotch-potch, an *omnium gatherum* of fact and myth; but we could at least feel sure that in each section all that had ever been known of the subject was given. The work was really beyond the power of any single individual, and, if it were to be brought to an end at all, should have been executed on some extensive plan of cooperation similar to that employed in Dr. Murray's English Dictionary. As an example of the minute care bestowed on each point, it may be mentioned that in dealing with "Jade" the author gives two Latin synonyms, two Chinese, thirteen Japanese, a Spanish, a Manchu, a Turkish, a Persian, an Arab, and a Maori synonym!

Lieut. B. Baden-Powell, Scots Guards, made an ascent in his own balloon from Aldershot on Monday last week. The weather at the time of starting (4.30) was threatening and the wind fresh from the north-east. On rising to a height of 4000 feet, a lovely cloudscape was seen, the sky overhead being clear and blue, and a sea of clouds stretching around with very distinct horizon. Below, the earth could be seen through the haze, on which the shadow of the balloon was thrown, a bright halo surrounding the car. The descent was made at a quarter to six, about twenty miles off.

Mr. H. O. Forbes writes:—In a note received from the ex-Governor of Timor (now in Lisbon) I learn that a violent earthquake was experienced in Dilly on November 11, which destroyed the hospital and also damaged the church and other edifices, but without loss of life.

The last number of the *Journal of the Straits Branch of the Royal Asiatic Society* (Singapore, 1883) has the continuation of Capt. Kelham's notes on the ornithology of the Straits Settlements and the western States of the Malay Peninsula; also a collection of Malay proverbs, by Mr. Maxwell. Mr. Cameron contributes a paper on the Patani, the most considerable river of the peninsula, which flows northwards into the Gulf of Siam. An article of extraordinary interest is that on *latah*, a nervous disorder among Malays, or rather the native name applied to

those who labour under the disorder. "It includes all persons of a peculiarly nervous organisation, ranging from those who, from their mental constitution, seem absolutely subservient to another's will, down to those who appear merely of a markedly excitable temperament." Numerous examples of the effect of this mysterious mental affection are added by the writer, Mr. H. A. O'Brien.

WE gladly notice the issue of three new numbers of the *Encyclopædia of Natural Sciences*, from the publishing house of Eduard Trewendt, in Breslau. The tenth number is now out of the *Alphabetical Manual of Zoology, Anthropology, and Ethnology* (part i. l. 36), which with this new instalment has completed its "F," and entered on its "G." The number referred to contains very valuable articles contributed by Gustav Jäger, Reichenow, von Mojsisowics, Roeckl, von Hellwald, Sussdorf, and others. Nos. 19 and 20 of the second part of the collective work have also appeared, both belonging to the *Dictionary of Chemistry*, edited by Ladenberg. Among other valuable articles in No. 19, by Ladenburg, Biedermann, Weddige, and Jacobsen, "Azoverbindungen," by Heumann, and "Benzœsäure" by Weddige, are treated with special completeness. In No. 20 are articles by Engler, Drechsel, Biedermann, and others. These two numbers bring the *Dictionary of Chemistry* to the end of "B." We again wish all success to this comprehensive collective work on the natural sciences.

MM. HENRY are experimenting with a system of photography for double-stars, in order to determine their distance and position angle. They have already obtained good results on about twenty stars in various constellations.

M. LEVEAU has been appointed Astronome Titulaire at the Paris Observatory, in place of the late M. Yvon Villarceau.

IN a small pamphlet published at Saigon ("Memoire sur les Poissons de la Rivière de Hué," C. Guilland et Martinon), M. Tirant, the Administrator of Native Affairs, has given a catalogue of the fish to be found in the river of Hué, the capital of Annam, and in the adjacent lagoons. These latter are exceedingly numerous, running parallel to the sea for miles, and are filled during the rainy season by the overflow from the rivers. They are employed as reservoirs for the fish supply of the capital. In them, and in the river itself, Dr. Tirant states he procured seventy new species of fish.

INFORMATION has recently been received in Paris of the death of M. Bruel, one of the most enterprising of French explorers in Cochin China. He was murdered by pirates on January 18 in Cambodia, on the frontier of the Laos country.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* ♂) from Continental India, presented by Mr. A. MacDonnett Green; a Common Fox (*Canis vulpes*), British, presented by Miss Bertha Haig; a Herring Gull (*Larus argentatus*), European, presented by Mr. R. Morton Middleton, jun.; a Green Lizard (*Lacerta viridis*), European, presented by Mr. J. H. Leech; three Russell's Vipers (*Vipera russelli*) from Ceylon, two Indian Rat Snakes (*Pytas mucosa*), an Indian Python (*Python molurus*), an Indian River Snake (*Tropidonotus quincunciatus*), two Indian Cobras (*Naia tripudians*) from India, presented by Mr. Gerald Waller; a Gray Ichneumon (*Herpestes griseus*) from India, a Short-headed Phalanger (*Belideus breviceps*) from Australia, three Lesser Birds of Paradise (*Paradisea minor*), two Red-sided Eclectus (*Eclectus pectoralis*) from New Guinea, a Chattering Lory (*Lorius garrulus*), a Three-coloured Lory (*Lorius tricolor*) from Moluccas, deposited; a Dusky Parrot (*Pionus violaceus*) from Guiana, received in exchange; a Smooth-headed Capuchin (*Cebus monachus*) from South-East Brazil, a Severe Macaw (*Ara severa*) from Brazil, two Schlegel's Doves (*Chalcopelia puella*), a Buffon's Touracou (*Corythaix buffoni*) from West Africa, a Diademed Amazon (*Chrysotis diademata*), a Yellow-shouldered Amazon (*Chrysotis ochroptera*) from South America, a Banded Aracari (*Pteroglossus torquatus*) from Central America, received on approval; a Mediterranean Seal (*Monachus albiventer*) from the Mediterranean, two Chinchillas (*Chinchilla lanigera*) from Chili, an Anaconda (*Eunectes murinus*) from South America, purchased.

OUR ASTRONOMICAL COLUMN

THE SOUTHERN COMET (ROSS, JANUARY 7).—Adopting Mr. Tebbutt's elements copied into this column last week, we have the following positions of the comet observed at Melbourne and Windsor, N.S.W., for 6h. Greenwich mean time:—

1883	R.A. h. m. s.	N.P.D. ° ′	Log. distance from Earth	Sun
Dec. 16	17 4 30	93 56·9	0·0561	9·6151
18	17 12 4	94 3·2	0·0232	9·5758
20	17 21 35	94 34·4	9·9864	9·5393
22	17 33 53	95 44·7	9·9463	9·5102
24	17 49 54	97 50·8	9·9046	9·4934
26	18 10 31	101 6·2	9·8651	9·4930
28	18 36 2	105 29·2	9·8332	9·5090
30	19 5 47	110 35·5	9·8144	9·5376

This ephemeris, founded upon an orbit which is certainly not open to material correction, enables us to decide that the supposed comet which was seen in Tasmania on the mornings of December 25 and 27, rising a few minutes before the sun, could not have been the comet detected by Mr. Ross on January 7, which on those mornings would not rise (at New Norfolk, for instance) till upwards of forty minutes after the sun; on December 25 the sun rose there at 4h. 21m., the comet at 5h. 2m.

It is not easy to reconcile the estimate of brightness at Melbourne on January 11 with that of Mr. Tebbutt on January 19. Mr. Ellery writes to the *Observatory* that on the former evening the comet disappeared in a faintly illuminated field, simultaneously with a tenth-magnitude star, while Mr. Tebbutt considered it on January 19 to be just beyond unassisted vision; yet the ratio of the theoretical intensity of light on the former date would be to that on the latter as 2·9 to 1.

The comet appears to have been well above the horizon in European latitudes before daylight, previous to the perihelion passage. Between December 17 and 21 it rose at Greenwich about 5h. 40m. a.m., but the presence of the moon would have rendered its discovery difficult. It was nearest to the earth on the morning of January 1, the distance being then 0·646 (the earth's mean distance from the sun = 1).

THE ASPECT OF URANUS.—At the sitting of the Academy of Sciences of Paris on April 21, M. Perrotin presented a note on the aspect of Uranus, from observations made with the 15-inch equatorial at the Observatory of Nice. On March 18 he had remarked, in company with Mr. Lockyer, a bright spot near the lower limb of the planet, as seen in the inverting telescope. Further observations showed that it was near the equator of Uranus. It was a very difficult object, and much uncertainty existed as to its exact position; it was better seen as it approached the limb. It was observed on April 1 about 11h., at the northern extremity of the equatorial diameter, and on the next night about 10h. [illegible]0m., at the southern extremity: it occupied the same position on April 7 at 10h. 30m., and April 12 at 11h. These observations, M. Perrotin adds, made at the limits of visibility, required very favourable conditions, and being aware of the possibility of illusion in such a case, he invites the attention of observers possessed of powerful optical means, in order to control his own impressions. The appearance and the indeterminateness in the duration of the phenomenon on April 1, when the images were best, rather point to a luminous belt than to a single spot, which introduces uncertainty in the times of the observations; with due regard to this, M. Perrotin finds a fair agreement with the assumption of a rotation not differing much from ten hours. On April 12 Mr. Trépied was present, and confirmed the impressions received by the Nice astronomer; he also remarked in the bright part a condensation which had previously escaped notice.

By "diamètre equatorial" we presume M. Perrotin refers to the diameter in the plane of the orbits of the satellites.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The following courses of lectures are being delivered this term:—

Mathematics—Prof. Stokes, Optics; Prof. Darwin, Theory of Potential and Attractions; Trinity College, Mr. Glaisher, Theory of Errors, Mr. Ball, Higher Solid Geometry, Mr. J. J. Thomson, Dynamics of a Rigid Body, Mr. Rowe, Higher Integral Calculus and Abel's Theorem, Mr. Forsyth, Thermodynamics; St. John's College, Dr. Besant, Analysis, for Schedules II. and III., Mr. Pendlebury, Laplace's and Bessel's Functions, Mr. Webb, Elementary Rigid Dynamics; Pembroke College, Mr. Burnside, Hydrodynamics; Emmanuel College, Mr. Webb, Elasticity.

Physics—Trinity College, Mr. Trotter, Electricity and Magnetism, Mr. Glazebrook, Elementary Physics; Cavendish Laboratory, Mr. Shaw, Elementary Physics; St. John's College, Mr. Hart, Elementary Electricity, Practical Physics, Cavendish Laboratory; Advanced Demonstrations in Light and Sound; and Elementary Demonstrations in Optics and Electricity.

Chemistry—Prof. Liveing, Course of Examinations and Personal Instruction of those who have attended his general course in the last two terms; Mr. Main, General Course, including Carbon Compounds; Mr. Pattison Muir, Non-Metals, and Elementary Organic; Mr. Sell, Elementary Chemistry; Mr. Scott, Gas Analysis; Mr. Lewis, Catechetical Course.

Practical Chemistry—Demonstrations for 1st M.B. by Mr. Sell and Fenton; Demonstrations in Qualitative Analysis (Sidney College), Mr. Neville; Practical Courses at St. John's and Caius College Laboratories.

Mineralogy—Prof. Lewis; and two Courses of Elementary Demonstrations.

Mechanism—Prof. Stuart, Differential and Integral Calculus for Engineering Students; Mr. Lyon, Machine Construction and Heat; Mr. Ames, Surveying and Levelling.

Physiology—Elementary, Prof. Foster; Structure and Function of the Central Nervous System, Mr. Langley; Advanced Physiology of Respirations, Dr. Gaskell; Preparation for 2nd M.B., Mr. Hill.

Human Anatomy—Prof. Macalister, Anatomical Basis of Anthropology, Advanced; Demonstrations and Dissections.

Elementary Biology, Mr. Sedgwick; Morphology of the Vertebrata, Mr. Sedgwick; Mollusca and Tunicata, Mr. Weldon; Mammalia, Mr. Gadow.

Botany—Prof. Babington, Structural and Systematic; Morphology, chiefly Cryptogamic, advanced, Dr. Vines; Demonstration Lectures on Physiology, Mr. F. Darwin; Demonstrations in Systematic Botany, Mr. Potter.

Geology—Stratigraphy, Local, Prof. Hughes; General Course, Carboniferous to Recent, Dr. R. D. Roberts; Palæontology, Elementary, Mr. T. Roberts; Microscopic Petrology, Mr. A. Harker; Climatology, Mr. E. Hill; Metamorphism, Mr. Marr; Field Lectures, Prof. Hughes.

SOCIETIES AND ACADEMIES

LONDON

Royal Meteorological Society, April 16.—Mr. J. K. Laughton, M.A., F.R.A.S., vice-president, in the chair.—J. Y. Davidson and T. Wright were elected Fellows of the Society.—The following papers were read:—On the origin and course of the squall which capsized H.M.S. *Eurydice*, March 24, 1878, by the Hon. Ralph Abercromby, F.R.Met.Soc. It will be remembered that the *Eurydice*, which was a full-rigged corvette, when passing Ventnor in the Isle of Wight, running free before a westerly wind, with all sails set, was struck by a sudden squall from the north-west; and before sail could be shortened she went on her beam ends, and the lee ports being open, she filled and foundered. The author has investigated the character of the weather preceding and following the day in question, and finds that the squall was one belonging to the class which is associated with the trough of V-shaped depressions. The squall, which originated in the north of England, swept across the Isle of Wight at a rate of about thirty-eight miles an hour. The V-depression was of an uncommon class, in which the rain occurs after the passage of the trough, and not in front of it, as is usually the case. The weather generally for March 24 was unusually complex, and of exceptional intensity, and for this reason some of the details of the changes cannot be explained.—Waterspouts and their formation, by Capt. J. W. C. Martyr.—The weather forecasts for October, November, and December, 1883, by C. E. Peek, M.A., F.R.Met.Soc. This is a comparison of the weather indicated in the forecasts of the Meteorological Office with that actually experienced at Rousdon in Dorset.—On certain effects which may have been produced in the atmosphere by floating particles of volcanic matter from the eruptions of Krakatoa and Mount St. Augustin, by W. F. Stanley, F.G.S. In this paper were given details of a microscopical examination which had been made of some dust that fell, to the thickness of about two inches, upon the deck of the bark *Arabella*, in lat. 5° 37′ S., long. 88° 58′ E., at about 1000 miles from Krakatoa, and supposed to be from the eruption of that volcano. The dust under examination was contained upon a single microscopic slide. For the convenience of discussion of the subject the visible forms were separated into eight different kinds of particles:—(*a*) Small masses and single crystals of mineral matter visible by polarised light only. These were principally of augite and of certain felspars. (*b*) Very thin chips and scales of the above. (*c*) Very small masses of dense ordinary pumice. (*d*) Fractured chips of the above with one thin edge. (*e*) Light apparently *overblown* pumice in relatively large thin plates. (*f*) Fractured parts of *e*, but of larger bubbles traversed by seams upon which septa normal to the surface formerly existed. (*g*) Fractured parts of *e*, but of larger plates, with a thicker seam on one edge or on one corner only. (*h*) Thin glassy plates of *e*, formerly of relatively much larger size. These are of equal thickness throughout, and generally with one hollow surface. The particles *a* and *b* form only about half to one per cent. of the mass, the whole of the remainder being of the different forms of pumice described. The particles *g* and *h*, as being much the lightest in proportion to their extent of surface, were most dwelt upon. These particles, which the author termed *bubble-plates*, are of irregular, angular forms. They measure under the microscope, in different directions, from about ·5 to ·05 mm. The thickness of the plates is fairly uniform, varying between ·001 and ·002 mm. When there is a seam on one edge, the plate is smaller, and thickens towards the seam. By taking the interior part of a large mass of pumice and breaking it up into fine dust, some similar forms may be discovered. These plates being of quite transparent, volcanic glass (obsidian), they are invisible under the microscope, by direct light; but being placed in a medium of higher refractive power, as Canada balsam, they become clearly defined under oblique illumination, above a spot lens, with careful adjustment. Mr. Stanley suggested that these thin plates were from overblown bubbles of volcanic glass such as forms the mass of pumice; that most probably they were projected from about the centre of the volcanic chimney, where they could maintain a melting temperature until they reached the higher atmosphere; under which conditions the internal steam in each separate bubble would expand in volume through release of external pressure until the bubbles burst in the very thin fragments shown. These thin forms of bubble-plates, having great surface in comparison with their very small masses, were such as were eminently adapted to float in atmospheric currents to great distances. As such particles would descend with their convex sides downwards, they would also be especially adapted to reflect the sun's rays, when the sun sank to the horizon, whereas when the sun was at greater altitude his rays would pass through them nearly unobstructed. It was therefore proposed that the after-glow so often observed since the eruptions of Krakatoa and Mount St. Augustin was possibly due to reflection from these thin plates.

DUBLIN

Royal Society, March 17.—Section of Physical and Experimental Science.—Howard Grubb, M.E., F.R.S., in the chair.—On the success of an instrument for completing the optical adjustment of reflecting telescopes, by G. Johnstone Stoney, M.A., D.Sc., F.R.S., vice-president of the Society. The author had been astronomical assistant to the late Earl of Rosse, and while in charge of his observatory became impressed with the importance of increasing both the degree of accuracy and the facility with which reflecting telescopes can be adjusted. At the Cheltenham meeting of the British Association in 1857 he described an instrument designed to attain these ends, but had no opportunity of testing its performance till two years ago, when a twelve-inch mirror came into his possession of exquisite defining power, figured by the late Mr. Charles E. Burton, B.A., F.R.A.S. This mirror is mounted as a Newtonian telescope.

The collimator proposed in 1857 was made for it last autumn by Mr. Howard Grubb, M.E., F.R.S., and its performance has been fully tested with the most satisfactory results during the present observing season. The new collimator is a short telescope of eleven inches focus and two inches aperture, which, when used, is to be inserted into the eyepiece-holder of the large telescope. A spark between platinum points is produced in the focus of this instrument by a small Rhumkorff's coil such as those sold with toy apparatus, and the light of the spark emerging from the collimator is reflected by the small mirror of the Newtonian, and so reaches its large mirror. By pushing the eyepiece and platinum points of the collimator a little inside its focus, the beam of light, as it passes down the large telescope, is rendered slightly divergent, and falls normally on the large mirror. If everything is in perfect adjustment, the beam of light will then, after reflection by the large mirror, retrace its steps, and, recentering the collimator, will form an image coincident with the spark. Any want of adjustment is at once betrayed by the image in the field of view of the collimator not being coincident with the spark. On commencing the night's observing, the mirrors of the large telescope are first adjusted in the usual way. The collimator is then put into the eyepiece-holder, and if the telescope has been tolerably well adjusted, the image of the spark will be found not farther from the spark than a quarter or a third of the field of view of the eyepiece of the collimator. The adjustment is then completed in the following way:—The eyepiece-holder, instead of being rigidly attached to the tube of the telescope, is mounted on a triangular plate fastened to the side of the telescope by screws acting against springs at the corners. By these screws the line of collimation of the eyepiece-holder can be slightly altered, and by moving them the image of the spark is made to coincide with the spark. The instrument is then in a condition of optical adjustment vastly more perfect than has hitherto been attainable with reflecting telescopes. This whole process occupies less than half a minute, and is so easy of application that the author is in the habit of repeating it every time the telescope is moved to a fresh object. He is rewarded by having the last degree of refinement applied to the adjustment of his telescope in using it upon every object, an advantage the importance of which will be appreciated by every astronomer who uses a sufficiently fine mirror and is working on a sufficiently good night.—Mr. J. Joly, B.E., read a paper entitled "Notes on a Microscopical Examination of the Volcanic Ash from Krakatoa." The ash examined was part of some which fell on board the Norwegian barque *Borjild* while she lay at anchor off the great Kombuis Island on August 27, 1883. Her position was some 75 miles to the north-east of Krakatoa, a strong south-westerly gale prevailing at the time. She was hence most favourably placed for receiving good samples of the dust. A specimen of the floating pumice, picked up by the *Borjild* in the Straits of Sunda, was compared with the ash. Microscopically they were found to present the same features. Two species of pyroxene occur—a monoclinic and a rhombic variety. The first was augite; the second presents many of the optical characteristics of hypersthene. Both contain much magnetite. A triclinic felspar is very abundant, showing many different crystalline shapes. The identity of many of these with the triclinic felspar is shown by their occurrence, twinned with and superimposed upon crystals presenting undeniable plagioclastic characteristics. They show small angles of extinction. The presence of sanadine appeared doubtful. Iron pyrites was found in the ash, both embedded in vitreous fragments and free, as aggregations of cubes, showing the striations at right angles for adjacent faces. Magnetite is abundant. The frequency of lines of growth on the felspars seemed indicative of a comparatively tranquil formation. Most of the crystals showed a fine coating—much pitted and reticulated—of vitreous matter. A sudden mechanical separation from a viscous magma would explain this appearance, which somewhat resembled that produced by rapidly separating two flat surfaces compressing a viscous substance. Organic remains were found abundantly in both ash and pumice. A foraminiferal shell, very perfect, was found in the ash, and an other in the pumice. Fragments, apparently of some algæ, were found plentifully in the former.—Dr. R. S. Ball, F.R.S., exhibited Mr. Common's photograph of the great nebula in Orion.—Prof. G. F. Fitzgerald, F.R.S., exhibited Ayrton and Perry's new spring ammeter.

Section of Natural Science, W. Frazer, F.R.C.S.I., in the chair.—On spherical or globular phosphorites of Russian Podolia, by Prof. J. P. O'Reilly, C.E.—Catalogue of Vertebrate fossils from the Siwaliks of India, by R. Lydekker, B.A., F.G.S., F.Z.S. Communicated by V. Ball, M.A., F.R.S.—On the action of waves on sea-beaches and sea-bottoms, by A. R. Hunt, M.A., F.G.S. Communicated by Prof. A. C. Haddon, M.A., F.Z.S. After detailing the conflicting views put forward by various authors, Mr. Hunt discusses Mr. Scott Russell's theory of oscillatory waves being converted into waves of translation, with observations and experiments to disprove it. The author then treats of the action of waves, currents, and wind currents on beaches, shingles, and sandbanks as observed in the neighbourhood of Torquay, and describes experiments conducted in a specially constructed tank.

Edinburgh

Royal Physical Society, April 23.—Dr. Traquair, F.R.S., in the chair.—Mr. Hugh Miller, A.R.S.M., read a paper on boulder-glaciation and striated pavements. Starting from local observations made near Edinburgh by Charles Maclaren and Hugh Miller upon the glaciation *in situ* of boulders and boulder pavements in the till, the author has been led to the conclusion that boulder-glaciation *in situ*, registering the ice-movement during the formation of the till, is extremely common. The glaciation of the county of Northumberland, to which he referred in passing, may be roughly divided into upland-glaciation, valley-glaciation, and glaciation of the seaboard. All these are registered equally well in the striation of the larger boulders (whether singly or in groups) as in that of the rock below. He confirmed the older observations that the glaciating agent was the same in both the rocks and the boulders, adducing the fact as strong evidence of the glacier origin of the deposit. That floating ice should striate in fixed directions so many blocks lying in soft mud at the sea-bottom he regards as impossible. As registering changes in ice-movement, the intercrossing of erratics, and a distinction between successive boulder-clays, this widespread glaciation of boulders *in situ* may prove of general importance and a distinguishing mark of the true till.

Paris

Academy of Sciences, April 21.—M. Rolland in the chair.—Letter of condolence to the family of the late M. Dumas from the *savants* of Geneva.—On a theorem of Kant relating to the celestial mechanism, by M. Faye.—On the scale of temperatures and on molecular weights, by M. Berthelot. The author endeavours to show that a profound study of specific heats tends to establish the fact that heat, which resolves compound molecules into their elements, has also the effect of resolving the highly complex groups of particles which constitute the bodies hitherto regarded as *elementary*.—On the optical identity of the crystals of herderite of Ehrenfriedersdorf with that of the State of Maine, by M. Des Cloizeaux.—Account of a young gorilla recently brought from the Gaboon and now in the menagerie of the Natural History Museum, Paris, by M. Alph. Milne-Edwards. This specimen is described as of a much more ferocious character than the chimpanzee or orang-utan, and greatly inferior in intelligence even to the gibbon.—Note accompanying the presentation of the marine charts and hydrographic documents offered to the Academy by the Depot of Charts and Plans on behalf of the Department of Marine, by M. de Jonquières.—On the separation of phosphoric acid in arable lands, by M. de Gasparin.—On the speed attained by Lapps with their snowshoes; extract from a letter addressed by M. Nordenskjöld to M. Daubrée. From the result of races instituted for the purpose of determining this point, an average speed of over six miles per hour was verified at Quickjock in Lapland.—Further observations on the present appearance of the planet Uranus as observed at the Observatory of Nice during the month of April, by M. Perrotin.—Changes observed in the rings of Saturn, by M. E. L. Trouvelot. From continued observations made since the year 1875 at the Meudon Observatory the author is able definitely to confirm the conclusion already arrived at, that the rings, so far from being fixed, are extremely variable.—On surfaces of the third order, by M. C. Le Paige.—On uniformly inclined surfaces and proportional systems, by M. L. Lecornu.—On the principle of the prism of greatest thrust, laid down by Coulomb in the theory of the limited equilibrium of sandy masses, by M. J. Boussinesq.—On the diffusion of light through unpolished glass or metal surfaces, by M. Gouy.—On the propagation of sound through gases, by M. Neyreneuf.—On the boiling-point of oxygen, air, nitrogen, and the oxide of car-

bon under atmospheric pressure, by M. S. Wroblewski.—On a metallic radical, by M. P. Schutzenberger.—Determination of the densities of the vapours of the chloride of glucinium, by MM. L. F. Nilson and Otto Pettersson.—On the neutral molybdate of didymium, and on the equivalence of didymium, by M. Alph. Cossa.—On the curves of solubility of salts, by M. A. Étard.—On the bark of *Xanthoxylum caribæum*, Lk., as a febrifuge, by MM. Heckel and Fr. Schlagdenhauffen.—On the application of the digester for the destruction of microbes in liquids, by M. L. Heydenreich.—On some siliceous spicules of living sponges obtained from the dredgings executed during the last expedition of the *Talisman*, by M. J. Thoulet.—On the generic relations of *Orbulina universa* with Globigerina, two illustrations, by M. C. Schlumberger. From the comparative study of these organisms the author infers that the dimorphism of the Foraminifera is an initial character resulting from two original forms.—On the action of heat on the phenomena of vegetation: (1) on the development and direction of the roots; (2) on the heliotropism of certain plants, by M. A. Barthélemy.—On marine and fresh-water deposits considered from the economical standpoint, according as they are or are not sulphuretted; alluvia of the Durance, by M. Dieulafait.—New report on the diamantiferous deposit at Grão Mogol, province of Minas Geraes, Brazil, by M. Gorceix.—On the bones of the head of the Simœdosaurians, and on the various species of this extinct reptile found in the Cernay formations in the Rheims district, by M. V. Lemoine.—Note on the crepuscular phenomena observed at the Imperial Observatory of Rio de Janeiro during the winter months of 1883-84, by M. L. Cruls.—Note on the scientific mission to Cape Horn 1882-83 in connection with the question of the periodicity of barometric oscillations, by M. Ch. V. Zenger.

BERLIN

Physical Society, March 21.—Dr. Frölich spoke of some modifications of Wheatstone's bridge which had been applied to the measurement of the electric resistance of galvanic elements and batteries. Wheatstone's bridge consisted, as was known, of a wire quadrilateral and two wire diagonals. Of the two diagonals one contained a battery of constant electromotive force, the other the galvanometer. In these circumstances the resistances of the four lateral wires showed the proportion $W_1 : W_3 = W_2 : W_4$. For the purpose of measuring the resistance in a galvanic battery, the arrangement was so far empirically changed that the battery to be measured was inserted in one of the lateral wires. A second empirical method consisted in inserting the galvanometer into one diagonal wire and interrupting the second; the battery to be measured was placed in a lateral wire. Dr. Frölich showed that both arrangements were only modifications of Wheatstone's bridge. The way in which these modifications originated might be conceived by supposing that the bridge was formed of cords, and that the angles of the square were successively shifted; the proportion which applied to Wheatstone's bridge would still hold in the new case. Dr. Frölich laid down a general law applicable to all individual cases. If in a Wheatstone bridge an element be inserted into each wire, while one diagonal wire contained the galvanometer, and the other was interrupted, if, moreover, on opening this wire, the electromotive force in the other diagonal remained unchanged, then the proportion above stated between the resistances of the lateral wires would still hold. Whether this general law included such a case as could be applied practically and with certainty to the measurement of the resistance of elements must be determined by experience.—Dr. Frölich then gave a report on the continuation of his measurements of solar temperature. At a former sitting he communicated the measurements he had made during the previous year. These measurements yielded an almost equal result on June 29 and July 1, an increase of solar heat of 6 per cent. over this last estimate on August 14, and a value pretty nearly equal to that of July 1 in the middle of October. Since then doubts had been expressed as to whether the calculated increase of solar heat in August corresponded with the fact, seeing that the amount of the difference was not so much greater than might be accounted for by assuming an error, not easily avoided, in an observation. In opposition to this consideration, Dr. Frölich contended that, even if it were claimed that the difference would have to be three times greater than any error in observation which might probably occur, the increase in August had such a high degree of probability in its favour that one might bet 22½ to 1 for its accuracy. All doubt, however, on the matter was completely removed by two measurements Dr. Frölich made on February 19 and March 17. Both measurements yielded pretty nearly equal values of solar heat, and one was 15 per cent. higher than the estimate of the middle of October last year. In this case the probable error was surpassed eight times. Dr. Frölich was of opinion that the increase of solar heat in August was connected with an assumed formation of sunspots, and seeing that the spots were bound up with the magnetism of the earth he made inquiries with a view to ascertaining the state of the terrestrial magnetism at that time. From the average of the reports collected by him he found that in correspondence with the increased solar heat in the middle of August there was a diminution of the earth's magnetism.—At the close Dr. Frölich produced a large lump of magnesium as the product of an electrolytic industry. The piece was wrought in a factory according to a patented method based essentially on the melting of chloride of magnesium, and decomposing it in the melted state by an electric current.

VIENNA

Imperial Academy of Sciences, March 20.—L. Martin, on the polydimensional argument.—R. von Drasche, on some new and less-known ex-European Ascidia.—T. Latschenberger, on testing and determining ammonia in animal fluids.—W. Fossek, synthesis of dyad alcohols by action of alcoholic potash on aldehydes.—On the action of phosphorus trichloride on aldehyde, by the same.—F. Wiesner, on geotropic curvature of roots.—F. W. Dafert, synthesis of glycuronic acid from mannite (sealed packet).—K. Olszewski, determination of density and of coefficient of expansion of liquid oxygen.—Determination of the temperature of solidification of some gases and liquids, by the same.

April 3.—A. Adamkiewicz, preliminary communication on new stainings of the spinal cord, part ii.; results obtained by staining the diseased spinal cord with saffronine.—M. Loewit, contributions to theory of blood-coagulation, part i.; on the coagulating power of the blood-disks.—A. Lustig, contributions to development of gustatory buds.—T. V. Tanowski, on direct substitution-products of azobenzene and on an asymmetrical trinitroazobenzene.—E. Witlazil, on polymorphism of *Chætophorus populi*, L.—M. Strainsky, on tides and their reaction on the configuration of the earth's surface.—R. Benedikt and K. Hazura, on morin.—R. Benedikt and P. Julius, on diresorcin and diresorcinphthaline.—K. Hazura and P. Julius, on resorcin-ether.—P. Julius, on a new reaction of benzidine.

THURSDAY, MAY 8, 1884

A PLEA FOR A NATIONAL MARINE ZOOLOGICAL SURVEY

WHILST the influential meeting recently held at the Royal Society, for the purpose of founding a Society for the Biological Investigation of the British Coast, is still in the minds of naturalists, the present occasion is a fitting opportunity for the expression of opinions respecting the scope and aims of such an undertaking, as well as to suggest in what way zoological investigation in general may be more systematically directed than has hitherto been the case in this country.

The primary object of the newly-formed Society, as indicated in the resolutions passed at the preliminary meeting, is the establishment of a zoological station. This of itself is an important step in the right direction; and though much will depend on the thorough organisation and efficient management of the station, the hearty thanks of naturalists are already due to Prof. Ray Lankester for the energy and perseverance with which he has brought this desideratum within possible attainment. The establishment of a zoological station, however, or even of a number of stations at different parts of our seaboard, is not the only thing wanted. Neither should the maintenance of a single biological laboratory be the only aim of such a Society as the one proposed. Indeed it may be seriously questioned whether a Society is the best, or even a necessary, piece of machinery for the maintenance of a zoological station at all, excepting solely as a subscribing body, and even in this capacity its efficiency may prove inadequate. It is therefore to be hoped that the new Society will realise that there are broader and more extensive claims which zoology has a right to make in a country so peculiarly placed as Britain.

Few will deny that, notwithstanding the impetus given to the study of zoology during the last quarter of a century by the theory of evolution and the revelations of embryology, this branch of science appears in many respects to have been more backward than several of the kindred sister sciences in revising methods of investigation in accordance with the spirit of the age. Biology and morphology have of course made advances whose importance cannot be over-estimated; but it would seem that Zoology—in the wider sense—might well take a leaf out of the book of her much younger sister, Geology. Years ago, quite in the infancy of that science, national geology was placed upon a systematic basis by the establishment of the Geological Survey. The reason of that step is perhaps not far to seek. It stood mainly upon utilitarian grounds. The geologist was able to show that a knowledge of his science directly concerned the mineral wealth of the country, and that he offered as as it were the key to the then secret storehouses of coal, ores, and water, which were unmistakable synonymous terms for national wealth, advancement, and prosperity. It is quite unnecessary in the present place to do more than refer incidentally to the admirable manner in which the Geological Survey has fulfilled, and is still fulfilling, the purpose of its being. While constantly keeping in view the industrial applications of geology, it has at the same time never lost sight of the strictly scientific problems which the geological structure of the country presents in such abundance. Its success in both these departments may well point the argument that the zoologist has an equal share, and an equal power to assist, in the nation's welfare, besides possessing his own ample domain in science.

The insular position of this country naturally causes the sea fisheries and all that pertains thereto to be an important factor from a national and pecuniary point of view. The food, the habitat, the cultivation, the development, the enemies, and the diseases of fish all lie within the province of the zoologist; and it is to him alone that we can come for information on these questions, whereon the prosperity of our national fisheries depends, just as it is to the geologist that we go for direction as to the acquirement of the coal and ores that lie treasured beneath our feet, or as to the sources and quality of the water required for the supply of towns. On these grounds national marine zoology may claim an equally systematic method of investigation and an equal recognition as an important handmaiden to national wealth. Patriotism, as well as the desire for the advancement of human knowledge, would therefore urge with all possible earnestness the establishment of a national Marine Zoological and Physical Survey, whereby the fauna and the conditions of every portion of our coast should be carefully investigated. Apart from the unquestionable advantages that would thus be afforded to our fisheries, it is not too much to promise that by this means a greater amount of light would be thrown upon the life-histories of marine organisms, upon the variations of species, and the conditions upon which these depend, together with the solution of a greater number of important zoological problems than we could otherwise ever hope to attain. From a geological point of view, also, it is most desirable to have a better knowledge of the deposits now forming around our coasts. Other countries have already recognised these claims, and the fruition of their foresight is too well known to naturalists to need recapitulation here.

Such a scheme as the present naturally demands national encouragement and Government support. Many will of course say that the British Government is too much hampered and proverbially backward in assisting scientific projects to undertake what is here briefly indicated. May not, however, the want of success in obtaining assistance from Government be found to lie too frequently in the imperfect and partial manner in which application is made? Ministers and members of Government are too frequently "asked" in a private, unofficial manner whether support might probably be obtained for such-and-such an object; and should this happen to be one with which they are little conversant, it is only natural that the answer should frequently be unsatisfactory.

The establishment of a systematic and permanent Zoological Survey has, from its direct relation with a great national source of wealth, apart from its equally important scientific bearings, a logical claim which cannot be gainsaid; and it is scarcely to be supposed that a properly organised application would fail to be favourably received by the Government. In the event, however, of the prayer of such an application being rejected, the onus of neglecting an important British industry would obviously then rest on the shoulders of the Government; and scientific

men would at least have done their duty in urging its claims and pointing out whereby it might be protected and augmented. It unfortunately happens that up to the present time scientific men have brought no definite scheme or proposition of this kind directly before Government; and the onus of neglect may consequently in a certain sense be said to rest now at their door.

The honour of removing this responsibility lies directly within the scope of the newly-formed Society for Biological Investigation; for naturally no other body of men could more readily put themselves into communication with the various kindred societies throughout the kingdom, and thus obtain a unison of views upon this important subject. The next step would be to elect an influential representative deputation from the Society to wait upon the Prime Minister for the purpose of urging the appointment of a Parliamentary Commission to inquire exhaustively into the various subjects pertaining to a Zoological Survey.

THE ELECTRICAL CONGRESS OF PARIS, 1884

THE first Congress of 1881 has borne good fruit. It has not only brought about an *approchement* between electricians of all countries, but it has led to the adoption of an international system of measurement which will be in universal use. It is satisfactory to find that there are questions which can be amicably settled internationally. The Congress was divided into three Commissions which dealt with (1) electrical units, (2) atmospheric electricity and earth-currents, (3) standard of light. The first Commission virtually dealt with the length of a column of mercury of one square millimetre section which represented the ohm—it having been decided at the Congress of 1881 that this should be the unit of resistance. Many physicists had been working on this in different countries and on different methods. M. Mascart grouped the results in the following useful table:—

Methods	Experimenters	Column of Mercury in Centimetres
1. B.A.	British Association	104·83
	Rayleigh-Schuster	106·00
	Rayleigh (1882)	106·27
	H. Weber ...	106·16
2. Weber (I.) ...	Kohlrausch	105·81
	Wiedemann	106·19
	Mascart	106·33
3. Kirchhoff ...	F. Weber...	105·02
	Rowland	105·79
	Glazebrook	106·29
	Mascart	106·33
4.	Röiti	105·9
5.	Fr. Weber	105·33
6. Lorenz	Lorenz (first)	107·1
	Rayleigh	106·24
	Lenz	106·13
	Lorenz (second)	106·19
7. Weber (II.) ...	Dorn	105·46
	Fr. Weber	105·26
	Wild	105·68
	Baille	105·37
8. Heat	Joule	106·22

From this it appears that the figures obtained by the different methods were—

B.A.	106·21
Weber's I.	106·14
Kirchhoff's...	105·93
Lorenz	106·19
Weber's II.	105·47
Joule	106·22

The mean of which was 106·02, but 106 was taken as a round figure sufficiently near the truth for all practical and useful purposes. Hence the Congress decided that "the legal ohm should be the resistance of a column of mercury of one square millimetre section and of 106 cm. of length at the temperature of freezing," and a resolution was passed desiring the French Government to transmit this resolution to the different Governments, with a view of making its adoption international. It was decided that primary standards should be constructed in mercury, but that secondary coils should be made of solid alloys, which should be frequently compared among themselves and with the primary standard.

It was resolved that the ampère should be exactly 10^{-1} C.G.S. electromagnetic unit of current, and that the volt should be the electromotive force which maintained an ampere in a conductor whose resistance was the new ohm.

We can now congratulate ourselves upon having a scientific system of electrical units independent of any particular instruments or of any particular process. It is not absolutely exact. That is, the new ohm is not 10^9 C.G.S. units, but it is the nearest approach to it that can be practically attained. It will probably be known as the *Congress ohm*, to distinguish it from the true ohm (10^9 C.G.S.) or the B.A. ohm of 1864.

One subject of regret is that Prof. Rowland's measurements in Baltimore are not completed, and will probably not be ready before the end of the year. The United States Congress voted a large sum of money to enable this to be done. He is using a Planté secondary battery and employing three methods, viz. Kirchhoff's, Joule's, and Lorenz's. His well-known experimental skill has given much interest to this investigation of Rowland's.

The second Commission dealt with atmospheric electricity and earth-currents, and recommended that it was desirable to send each year to the Bureau International des Administrations Télégraphiques in Berne the reports that were collected in the different countries, so that they might be distributed to the different Governments.

The third Commission dealt with the standard of light, and it was decided, not without considerable opposition, that the unit for each simple light should be the quantity of light of the same kind emitted in a normal direction by a square centimetre of surface of fused platinum at the temperature of solidification, and that the practical unit of white light should be the total quantity of light emitted normally by the same source. This is a very unsatisfactory standard. It was accepted because there was virtually none other before. But it was obtained by only one observer (M. Violle); it is not portable; it is not even reproducible except at great expense, and it is so eminently impracticable that it is scarcely likely to be generally adopted. It is to be regretted that the British Association Committee on a Standard of White Light has not yet finished its work, but we may hope that at Montreal Capt. Abney will be able to give some results which will give us a better and more practical standard.

There was a universal consensus of opinion that the Congress had faithfully and earnestly done its work, and that the success of its labours and the rapidity of its action was due to the energy and ability of M. Cochery, the Minister of Posts and Telegraphs. Our English representatives were Sir William Thomson, Capt. Abney,

Prof. Carey Foster, Prof. Hughes, Prof. Fleeming-Jenkin, Mr. Graves, and Mr. Preece. The full text of the resolutions is as follows:—

"I. *Electric Units*, strictly so called. First Resolution: The legal ohm is the resistance of a column of mercury of a square millimetre cross-section and 106 centimetres in length at the temperature of melting ice. Second Resolution: The Conference expresses the wish that the French Government should transmit this resolution to the different States, and recommend an international adoption of it. Third Resolution: The Conference recommends the construction of primary standards in mercury conformable to the resolution previously adopted, and the concurrent employment of scales of secondary resistances in solid alloys which shall be frequently compared amongst one another and with the primary standard. Fourth Resolution: The ampere is the current the absolute value of which is ten to the power minus one in electro-magnetic units. Fifth Resolution: The volt is the electromotive force which maintains a current of one ampere in a conductor the resistance of which is one legal ohm.

"II. *Earth-Currents and Lightning-Rods*. First Resolution: It is to be desired that the results of observations collected by the various administrations be sent each year to the International Bureau of Telegraph Administration at Berne, which will make a digest of them and communicate it to the various Governments. Second Resolution: The Conference expresses the wish that observations of earth-currents be pursued in all countries.

"III. *Standard of Light*. Resolution: The unit of each kind of simple light is the quantity of light of the same kind emitted in a normal direction by a square centimetre of surface of molten platinum at the temperature of solidification. The practical unit of white light is the quantity of light emitted normally by the same source."

DR. JOULE'S SCIENTIFIC PAPERS

The Scientific Papers of James Prescott Joule, D.C.L., LL.D., F.R.S., &c. (London: Published by the Physical Society, 1884.)

OUR benefactors are oftentimes unrecognised! The writer of the present notice of our latest acquisition in scientific literature, takes credit to himself for having been the first to propose to Sir William Thomson the reprinting of his original papers. Seized with a great desire to possess those invaluable electrostatic papers, which, in 1867, could only be read in the original by those who were fortunate enough to have access to the *Cambridge and Dublin Mathematical Journal*, he urged that there must be many others by whom a reprint would be gladly welcomed. Thus was originated the reprint of the "Electrostatics and Magnetism."

The initiative being taken, we have now a second series from Sir William Thomson—part published, part in progress—intended to include all his mathematical and physical papers. Prof. Stokes also, under the influence of pressure and good example, has produced the first half of a reprint of his classical papers. Abroad we have collections of the papers of Prof. von Helmholtz and Prof. Kirchoff. Last at the present moment, but far from the least in importance or in general interest, we have the first volume of republished papers by Mr. Joule.

But what a debt of gratitude we owe to the Physical Society for its publishing enterprise—first for the publication of Prof. Everett's "Illustrations of the C.G.S. System," a book which has been helpful to every student of physical science; then for its graceful tribute to the memory of Wheatstone; and now for this fresh and most happy undertaking.

Before looking at the papers themselves, let us unburden ourselves of one or two remarks. The form of the book is admirable. The printing and the diagrams are all that can be desired. The accuracy of the author of the papers, who has personally undertaken the editing, appears in that there is scarcely a misprint to be found in the 650 pages. One serious want, and one only, we have felt, and it is this. Throughout the book there are many back references to previous papers. These references are given in footnotes exactly as they were given in the original papers, thus, *Phil. Mag.*, ser. 3, vol. xiii. p. 268. But what the reader of the book wants, nay absolutely requires, is the reference to the page of the reprint itself where the passage alluded to is to be found. May we be allowed to suggest this as an improvement for the second volume now promised?

To come to the papers themselves, almost one hundred in number. There is a considerable number of unconnected papers on a great variety of subjects, several on meteorological phenomena, six or eight on new instruments or modifications of instruments, a mercurial pump, an improved barometer, a new dip circle, a current meter, &c., in addition to his tangent galvanometer, and one or two others to which we will immediately refer more particularly; then we have a paper on utilisation of sewage; a note on the prevalence of hydrophobia; improvements in the common kite, &c.: all of considerable value. For the most part, however, the papers are on two or three classes of subjects very closely connected, and these are of superlative interest, containing, as they do, the germs, or rather affording the foundation, of the modern theory of energy.

Mr. Joule's papers are remarkable in form as well as in substance. Of mathematics there is scarcely a line: but what clearness, and depth, and penetration into the hidden things of Nature! Thus their interest is general to an unusual degree. To those who shun the labour of arriving at results by "chasing the ρ" through mazes of equations they are the perfection of clear exposition of fundamental principles. The mathematician, on the other hand, finds in them a model of concise expression, and results of experimental investigation stated in a form ready and convenient for being represented in mathematical symbols.

It is impossible within the limits to which these lines are necessarily confined to notice exhaustively the investigations themselves, or even the results arrived at. We must content ourselves with a brief reference to some of the most important.

The first subject which seems to have attracted the attention of Mr. Joule was that of magnetism and the electro-magnetic engine. His earliest papers are taken up with the description of novel forms of the electro-magnetic engine, and of experiments in this connection. In a very early paper he investigates the laws relating to

what is now commonly spoken of as the *back electromotive* force of a motor. In connection with these researches Mr. Joule obtained valuable results with regard to the construction and the efficiency of various forms of magnets, both permanent magnets and electro-magnets, and he was led also to improvements in the galvanometer which, in the form of the tangent galvanometer, he afterwards perfected.

These experiments led naturally to investigations on the connection between heat, electricity, and mechanical energy, and to a comparison between electricity obtained from chemical action and that obtained from magneto-electric machines, and also to an examination into the heat given out during electrolysis.

A paper of March 1841, on the heat evolved by metallic conductors of electricity and in the cells of a battery during electrolysis, is of special interest. It is here that the law is first announced that the heat developed by a current of electricity, whether through a metallic conductor or in an electrolytic cell, is proportional to the resistance and to the square of the current. It is proved that the whole heat generated by a voltaic battery is proportional to the chemical action which goes on in each cell of the battery multiplied by the whole "intensity" or electromotive force; and the localities at which the several portions of the heat developed in a compound circuit, are clearly distinguished, and the quantities of heat developed in each part are determined.

In this paper improvements in the galvanometer are referred to. A "degree of electricity," or unit-current, is defined as "the quantity of current electricity which is able to electrolyse a chemical equivalent expressed in grains in one hour of time." Hence the results in this paper, and in many others which follow and in which the same *degree* is used, are now easily reducible to absolute measure. His degree was somewhat less than two amperes, or one-fifth of the absolute C.G.S. unit. In this paper also he defines his *first unit of resistance*—a wire of copper ten feet long and 0·024 of an inch in diameter (about No. 23 B.W.G.); and it is curious and somewhat amusing to find that the copper wire which Joule used for this unit must have been preternaturally *bad!* If the wire had been of "conductivity" copper, such as is now universally insisted on, the resistance would have been 0·167 ohm. An easy calculation from Joule's results shows that the resistance must have been at least one-half more! It was not until the manufacture of the 1858 Atlantic cable was in progress that it was found that variations, not previously dreamed of as possible, were commonly to be met with in the conductivity of copper wire.

A most interesting paper on the electric origin of the heat of combustion, also in 1841, naturally follows that just referred to. It is in this paper that Joule determines the *electromotive force necessary to decompose water.* He finds it to be 2·8 of Smee's elements, and then proceeds to similar determinations for various chemical compounds used as electrolytes.

Space fails altogether for mentioning the multitude of interesting results, then perfectly unknown, which Joule brings out in these early papers. Many of them have played important parts in guiding and in assisting other investigators. We find tests recorded as to permanency of resistance coils. We have investigations of the resistance of electrodes of various materials in various electrolytic cells. Joule's early (1841 to 1844) determinations enabled Sir William Thomson in 1851 to calculate in absolute measure the electromotive force of a Daniell's cell. He found it to be 2,507,100 British absolute units or 1·0739 volt! It is doubtful whether we are assured of a better result at the present day.

We must notice next the series of papers containing Joule's researches on the dynamical equivalent of heat, unquestionably the most important of all his investigations. The complete and successful prosecution of this investigation belongs to Joule, and to Joule alone. The methods are his; the carrying out of the experiments is his. The result will ever be known under the honoured name of "Joule's equivalent."

It is interesting to notice the first germ of the idea, and to be enabled to follow, from its commencement to its conclusion, the series of experiments which gradually brought out the result with which we are now so well satisfied.

In a paper dated January 24, 1843, we find the first mention of the idea as follows:—

"The magnetic electrical machine enables us to convert mechanical powers into heat by means of the electric currents which are induced by it. And I have little doubt that, by interposing an electro-magnetic engine in the circuit of a battery, a diminution of the heat evolved per equivalent of chemical change would be the consequence, and this in proportion to the mechanical power obtained."

A note dated February 18, 1843, is as follows:—

"I am preparing for experiments to test the accuracy of this proposition."

The results of the experiments alluded to in the note just quoted were given to the British Association at its meeting at Cork, in a paper read on August 21, 1843, "On the Calorific Effects of Magnetic Electricity, and on the Mechanical Value of Heat." The experiments were made by rotating "an electro-magnet immersed in a vessel containing water between the poles of a powerful magnet, to measure the electricity thence arising by an accurate galvanometer, and to ascertain the caloric effect of the coil of the electro-magnet by the change of temperature in the water surrounding it."

Permanent steel magnets were first employed for producing the magnetic field, and afterwards a huge stationary electro-magnet was used for this purpose. The writer of the present notice well remembers the interest with which this great rough magnet and its accompaniments were viewed, by some of the foreigners who visited the Loan Collection of Scientific Apparatus at South Kensington in 1877.

Joule's conclusion, given to the British Association at this time was that the mechanical equivalent of a water pound-degree Fahrenheit of heat was 838 foot-pounds of work. In a postscript to this paper, of date August 1843, he says:—

"I have lately proved experimentally that *heat is evolved by the passage of water through narrow tubes.* My apparatus consisted of a piston perforated by a number of small holes working in a cylindrical glass jar containing about 7 lbs. of water. I thus obtained one degree of heat per pound of water from a mechanical force capable of raising about 770 lbs. to the heigh of

one foot, a result which will be allowed to be very strongly confirmatory of our previous deductions."

In 1844 we have a paper communicated to the Royal Society on "Changes of Temperature produced by the Rarefaction and Condensation of Air." This paper was not accepted by the Royal Society for its *Transactions*, and the *Philosophical Magazine* had the honour of publishing it! In 1845, in a paper read before the British Association, he describes experiments made by stirring water with a "sort of paddle-wheel" in a "can of peculiar construction;" and in 1846 this was followed by an important paper on "Heat disengaged in Chemical Combinations."

It was, however, in 1849 that his celebrated paper "On the Mechanical Equivalent of Heat" was communicated by Faraday to the Royal Society. This was the first of Joule's papers which was communicated to and *not* rejected by the Royal Society, and *it* was rewarded by a Royal Medal! In this paper he describes experiments (1) on friction of water; (2) (3) friction of mercury, two series of experiments; (4) (5) friction of cast-iron, two series. From all these he concludes:—

"(1) *That the quantity of heat produced by the friction of bodies, whether solid or liquid, is always proportional to the quantity of force expended; and*

"(2) *That the quantity of heat capable of increasing the temperature of a pound of water* [*weighed* in vacuo *and taken at between* 55° *and* 60°] *by* 1° *F. requires for its evolution the expenditure of a mechanical force represented by the fall of* 772 *lbs. through the space of one foot.*"

In 1867 a report was communicated to the British Association through the Committee on Standards of Electrical Resistance, containing the results of fresh experiments on the dynamical equivalent of heat. Finally, at the desire of this Committee, and aided by funds placed at his disposal by the British Association, Mr. Joule undertook a complete redetermination. This was commenced in 1870, and his report was given in 1878. Here is his conclusion, stated in the last two sentences of the present volume:—

"The equivalent at the sea-level and the latitude of Greenwich will therefore be 773·492 foot-pounds, defining the unit of heat to be that which a pound of water, weighed by brass weights when the barometer stands at 30 inches receives in passing from 60° to 61° F. With water weighed *in vacuo* the equivalent is finally reduced to 772·55."

It is impossible for us to do more here than mention some of the other papers contained in this volume. Perhaps among those which are of highest importance we should refer first to a short paper "On the Theoretical Velocity of Sound," in which outstanding difficulties are cleared up, and deductions as to the true relation between the specific heat of air, volume constant, and the specific heat, pressure constant, are brought forward. We have also important experiments on "Some Amalgams," in which their mode of production and characteristics are dealt with. A paper "On Surface Condensation of Steam" was largely conducive to the great improvement which the substitution of this method, for condensation by injection, has realised in the condensing engine of the present day.

In connection with his very earliest work Joule gave special attention to the construction of thermometers. He was the first to produce accurate thermometers in England, as Regnault did, just about the same time, in France. Joule's thermometers were made for him by Mr. Dancer of Manchester. In 1867 we have a paper "On the Alteration of the Freezing-Point," giving the results of the observations of five-and-twenty years on this curious phenomenon. In the present volume the paper is supplemented by observations carried down to December 1882.

We mention, lastly, his papers describing experiments to test the brittleness supposed to be imparted to iron castings by frost—experiments which, so far as they go, negative altogether the popular idea on the subject; and with this mention we must take our leave of the volume, expressing once more our deep appreciation of its value, and earnestly hoping for the speedy appearance of its promised companion.

LETTERS TO THE EDITOR

Long or Short Fractions for Great Natural and National Standards—Earth's Axis of Rotation

IN the two last numbers of the *American School of Mines Quarterly Journal* the learned President Barnard of Columbia College, New York, has involuntarily opened a question of far wider interest than the particular one with which he set out. For on his page 120 there stands the following remarkable statement:—

"The length of the polar axis of the earth is a quantity which may with strict truth be pronounced to be, up to this time, absolutely unknown."

Now if that really be so, the peoples of every civilised country on the face of the earth, who have been taxed during the last hundred years to the extent of millions and millions for the support of magnificent arc-of-the-meridian measuring establishments, have some right in common sense to rise with revolutionary wrath, and demand how those enormous sums of their money, given to determine the size and shape of the earth, have been expended. And when shall we know the far greater distance of the sun!

But the statement can only be true on some private interpretation which is needless to inquire into; for when we take the various lengths of the earth's axis of rotation as determined in modern times, and collected by President Barnard himself from very diverse sources indeed, we find them all to be coincident to four places of figures at least. And considering that for some other most important natural standards the world is apparently content with a certainty of two places of figures only, the officers of the several trigonometrical establishments of all the countries of Christendom deserve high praise, rather than blame, for the results they have succeeded in bringing out.

The mean of their last five measurements, as given by President Barnard for the polar axis of the earth, is

500,492,732·8 British inches,

the ten-millionth part of which is evidently

50·04927328 British inches;

though *he* has chosen to bring it out as a very different quantity indeed, viz. 49·273 British inches.

But the rather important point now to be discussed is, whether in practical use as a standard of measure, either on paper or for mechanical work, we should attempt to realise that long fraction; or be content with the

50·05 British inches,

at which, as quoted by the President, I had years ago ventured to assume the said ten-millionth of the earth's axis of rotation.

In place of merely, and perhaps vainly, *theorising* on the sub-

Pope Gregory's reformation of the calendar, by introducing the former (or something like it) in place of the latter quantity, caused sufficient disturbance to all the ordinary affairs of men in every nation when it was first adopted; and has some arguments which may be alleged in its favour still.

But if I read aright a recent tract by so consummate a physical astronomer as Prof. Simon Newcomb, he holds that the Gregorian alteration has done so much more harm than good, being quite a needless refinement, and is so totally unsuitable to calculations in physical astronomy, compared with the Julian year, that civilised nations should, and presently will, return to that year and reckoning, or "Old Style,"—leaving a few curious computers, whom it may concern, to prepare tables of corrections where they are absolutely required for their own abstruse and recondite purposes. C. PIAZZI-SMYTH

15, Royal Terrace, Edinburgh, April 26

The Ancestor of the Dipper (*Cinclus*)

IN NATURE for April 3 (vol. xxix. p. 524) the Duke of Argyll desires Mr. Romanes to prove "that the dipper once had an ancestor which began to dive in water, &c." The Duke well knows that such ancestry cannot be exhibited, but seems unaware that there are other *land* birds that are *divers* besides the dipper (*Cinclus*). I have often seen the winter wren dart or dive through a sheet of water, and remain in the damp and dripping space behind the little cascade. The water-thrushes (*Seiurus*, sp.) all wade in water, and often, seeing minute mollusca on the bottom of the stream, plunge both head and neck beneath the surface; so that, often for several seconds, a large part of the body is submerged. Now, these birds, like the winter wren, still have the plumage "pervious to water, and so *are* liable to be drenched and sodden"; but they have also the faculty of giving these drenched feathers such a good shaking, that flight is practicable a moment after leaving the water. Swallows, too, are often seen flying in and through spray and thin sheets of falling waters, yet with no detriment to their flight power. Certainly the water-thrushes or wagtails (*Seiurus ludovicianus*, *auricapillus*, and *noveboracensis*) have taken many preliminary steps towards becoming as aquatic as the dipper (*Cinclus*), and the winter wren, and even Maryland yellow-throat, are not far behind. The Duke can scarcely derive any comfort from the dippers; Mr. Romanes can. CHAS. C. ABBOTT

Trenton, New Jersey, U.S.A., April 18

Double-storied Houses and Concave Roofs

IN your issue of January 31 I notice a review of Mr. Im Thurn's book on the Indians of Guiana, in which attention is called to the manner in which a pile dwelling may be converted into a two-storied house, and Prof. Moseley's suggestion that the Swiss châlet did so originate is quoted, the general impression intended being apparently that this, in the majority of cases, is the origin of a double-storied dwelling. Now in that portion of the Himalayas lying south of the snowy range, to which my personal experience is confined, double-storied houses are almost universal, the lower story being used as a cattle-shed, the upper as a dwelling; at the level of the floor a platform is carried out from the building on one side at least, usually on three, or, if the house stands clear of the hillside, on all four sides. The only means of access to this platform and the upper story is by a ladder or flight of steps—it is difficult to say which it should be called—but it consists of the trunk of a tree split in half on the flat surface of which a series of notches are cut to give foothold; this is placed in a sloping position leading to the outside edge of the platform, or if, as is often the case, the platform is inclosed by boarding, through a hole in the floor. It will be seen that this is a principle of construction such as might easily have descended from a pile dwelling, and yet I cannot believe that this is the case; my reasons are: (1) there are no lakes in the Himalayas in which the habit of building on piles could have been acquired; (2) the houses are built of dry stone, strengthened at intervals by timber frames, these frames being without exception horizontal, and built into the wall in courses, such a thing as a vertical post being unknown, while had the style of and even five stories high, while those of the natives who are rich enough to afford it build three-storied houses, the ground-floor being used for the cattle, the intermediate one as a storeroom, and the upper one as the dwelling. On the other hand, the Kolis or Koltas, an aboriginal race who are as a rule the servants, or practically slaves, of the so-called Brahmin and Rajput land-owners, generally inhabit a single-storied cabin, but where these Kolis themselves own land and cattle, they, too, have double-storied houses. The true origin of this style of building lies, I fancy, in the fact that stone or wooden slabs are practically the only available roofing material, and the preparing and collecting these, not to mention the timbers required, forms a very serious part of the labour involved in building a house, and it is consequently an advantage to make one roof cover both the cattle and their owner rather than to undertake the labour and expense involved in two separate roofs.

In this connection there is a point to which I would wish to call attention. When first entering the Himalayas I was struck by the fact that, whereas the roofs of the villagers' houses were made with a single straight slope from ridge to eaves, those of the temples were as a rule steeper near the ridge, so as to present a concave outline, and as the ends were usually ornamented with deep weather boards fringed with pendent wooden ornaments, while the corners often had what can best be described as a wooden tassel, the appearance of the whole was decidedly Chinese; as I worked higher up into the hills, towards the region of the deodar, the origin of this construction revealed itself. Where deodar is abundant the roofs of the common houses, as well as of the temples, are made of split planks the whole width of the tree, and from 6 to 8 feet long, the ridge being made water-tight by a coping cut out of a single deodar-tree shaped into a ridge above, while in the lower side a V-shaped group is cut. If the row of planks next the ridge were set at a low angle, it might be difficult to fit this coping; but when the angle of the slope is high, the fitting is easier, and besides the beam by its weight grips the planks of the opposite slopes and holds them together effectually without the need of nails, a consideration of probably far greater weight at the time when this method of construction originated than at the present time. Thus the origin of the high slope near the ridge is explained, but to carry this high slope down to the eaves would necessitate the use of an inordinate amount of material, and so the second row of planks is arranged with a gentle slope; in those rare cases where the roof is large enough to require three separate rows of planks, the middle one is arranged generally with a slope intermediate between those of the two marginal ones, and the roof assumes a concave form. As deodar gets scarce the first roofs in which it disappears are those of the villagers' houses, and it is invariably the lower or gentle slope that is the first to be roofed with stone; then this spreads on to the steeper part of the roof, but here the slope has to be lessened or the slates nailed on. Where roofing slabs can be obtained, large and well-shaped, the latter alternative is adopted, and merely the deodar coping remains of the original wooden roof; as a last stage this too disappears, and the ridge is made water-tight by carrying the slates of one slope over the edges of those of the other. This style of roof, however, only persists where roofing slabs are obtained in such abundance and of such size that they can be cut to the desired shape; where slates are only procurable of small sizes and irregular shapes, the concave roof is soon found to be inapplicable, the higher slope near the ridge disappears, and the roof assumes the form of a single gentle slope, but in the temples the archaic form survives. I have called attention to this concave outline of roof because a similar concavity of outline in Chinese roofs is commonly said to be a survival from the time when the Chinese dwelt in tents; this can hardly be the true explanation, for, as Fergusson has pointed out, the Tartar tents, and those of all nomads with which I am acquainted, have a convex and not concave outline. I do not know whether there are in China any trees from which roofing slabs of good quality are or could be made, nor have I at present means of access to any books by reference to which I could settle this question, but if [illegible] be the case it is more probable that the concave outline originated as I have indicated above than in the manner suggested by Fergusson in his book on Eastern architecture.

This letter has already run to great length, but in conclusion I should like to add a few words anent the wooden ornaments already referred to. They are usually turned in a lathe, and in shape are not unlike the ninepins of our childhood, but the knob at the top is originally larger in proportion, and continued upwards into a tenon; the knob is then carved away so as to leave two interlocking loops, and the tenon is fitted into the weather board. At the corners of the roof there are often pendent disks of wood fringed with these ninepins, so as to form a sort of wooden tassel. These would answer well for a rude copy of bells which similarly fringe the roofs of the Chinese pagodas, and it is possible that there is a direct connection between the two, but in any case their association with a concave roof is at least a remarkable coincidence. B. D. OLDHAM

Camp Matil in the Himalayas, April 9

The Recent Earthquake

SINCE the earthquake of Lisbon in 1755 troubled the waters of the fish-pond, called Peerless Pool, in the London City Road, it has been a well-known fact that earth-waves had a direct influence in producing an alteration in the level of waters inland, as well as in producing tidal waves sweeping the coasts. The earthquake of Tuesday, April 22, has produced a marked, and, so far, permanent, change in the level of underground waters in the district most affected by the shock, but how far this influence extended there is not yet evidence to show, for, judging by past experience, it may probably prove that springs have increased in volume and the underground water-levels have been raised over the whole area affected by the recent shock, which includes the district lying between Broadstairs and Bristol, 165 miles from east to west, and from Spilsby to Ryde, 170 miles from north to south, and possibly beyond it. It will be of especial interest to know whether the Wealden area, which, as Mr. Topley has pointed out, was free from the more direct influence of the shock, experienced any rise in its underground waters.

At Colchester the water supply is derived from a deep artesian well in the chalk, the supply from which has slightly lessened during the past few weeks, necessitating the lengthening of the suction pipes; and the necessity of still further lengthening them was under discussion, when the Water Committee were agreeably surprised to find that the earth-wave of the 22nd had caused an increased flow of water, and a rise in the water-level of 7 feet, which has so far been maintained.

Earthquakes were described by Mallet "as the transit of a wave of elastic compression." This motion at Langenhoe produced fissures in the gravel walks of the vicar's garden, and at West Mersea opened a fissure a rod in length, which for a short time took off the springs which supply the village with very pure water, and when, after an interval, the pools in which the water accumulates were again full, it was found to be red and thick, and in some of them to be strongly mixed with chalk.

At Bocking the height of the water in Messrs. Courtauld and Co.'s well has been taken weekly for some years; the surface of the well is 137·07 feet above the mean sea-level, and the heights given represent the number of inches the water rises above the surface; the results are very remarkable, the highest previous reading being on Easter Monday, 1883, when it was 19 inches.

The following is the weekly record of the level of water in Messrs. S. Courtauld and Co.'s well, Bocking, Braintree, Essex. The observations are made at 6 a.m. on Monday mornings; no water is drawn from the well on Sunday.

1884		Inches		Corresponding period 188[illegible]		Inches
March	31	14½		April	2	13

,,	3	38½				
	5	42		May	6	15

The readings being weekly, and the earth-wave occurring the day after the record was taken, unfortunately a week elapsed before the remarkable rise was ascertained; after that the readings were taken daily, showing a continued steady rise in level.

These facts tend to show that the recent earth-wave has caused the fissures to open, and to permit a freer circulation of water, and that consequently the "cone of exhaustion" has been filled up with water; and that the only example of this effect so far received should be from chalky districts is not surprising when it is remembered, as Prof. Ansted pointed out, that, though the chalk absorbs water freely, it parts with it slowly, the water derived from chalk-wells being due more to water travelling in the joints and fissures than to the water stored in the chalk itself. It would appear probable that when the increased volume of water now running off, through the enlarging of the sectional area of the fissures, is again lowered by pumping, the old artesian gradients will be resumed, and that the present increase will be only temporary.

As Secretary of the Underground Water Committee of the British Association, I shall be glad to receive any further information on these phenomena. C. E. DE RANCE

Museum, Jermyn Street, S.W.

FROM recent observations I have concluded that the seismic vertical was at or near Dr. Green's house, close to the Strood or Causeway which connects the mainland of Essex with Mersea Island. The house was built in 1860, and is therefore new. I may here observe that (as I hinted before in former letters) the modern, cheaply-built cottages were not so much affected as the more ancient ones. The chimneys, walls, &c., of the latter were invariably destroyed, damaged, or cracked—the former seldom so. I was much surprised at this. The first thought naturally was that these "jerry-built" houses would be shaken down like a pack of cards. Is it that their very looseness of structure is in their favour, as compared with the stronger-built cottages of two and three hundred years ago? I have somewhere seen that in earthquake-visited centres the houses most secured from destruction are the loosely-built, low edifices. One can speak plainly on this matter, as no premium is required to encourage the development of "jerry-building."

Dr. Green's house is literally split and cracked in all directions, and the splits and cracks are the most vertical of any to be seen. The entire building was twisted on its foundations. At the south-west corner this is visible to the amount of about one inch and a half. Dr. Green informed me he was lifted up, as if from behind, and shot violently forward.

A friend of mine remarks (and I noticed the same fact in my note-book, but omitted inclosing it in my last communication) that the railway cutting at Wivenhoe appears to have broken the continuity of the undulations, for the houses contiguous to it are comparatively uninjured.

A noteworthy fact in connection with the recent earthquake, to which I can personally testify, and which appears to be the general experience of all the most trustworthy observers I have come across, is that the sounds or noises preceded the oscillations for an appreciable period of time. Mallet's experiments showed that the shock of an explosion travelled through wet sand at the rate of 951 feet per second. In Ipswich we are situated chiefly on drift sands and London Clay, and allowing that the earthquake shocks travelled through these strata at a more rapid rate, it is not likely to have been much more rapid. As sound travels at the rate of 1118 feet per second, it is very probable that the noise accompanying the earth-movements preceded the oscillations

Mr. Wilkins, the well-known yacht-builder at Wivenhoe, tells me he was standing at the time the earthquake occurred in the yard, and his first impression was that a new yacht he was looking at was heeling over, and he called out so to his workmen in the shop close by. Then followed the crash of the tall chimney and the rending of the walls. The workshop has an upper floor, with windows on each side, and, as he stood in the yard, Mr. Wilkins says the oscillatory waves were such that he was enabled to look right through these windows, so as to see the falling chimneys of the buildings on the other side. He calculates that there must have been a rise and fall of the ground of 2 feet 9 inches to have enabled him to do this.

On Saturday, May 3, the members of the Ipswich Scientific Society made an excursion to Langenhoe and Peldon, and Mr. Henry Miller, C.E., the honorary secretary, kindly took the following exact measurements of the rents seen in a building adjoining Peldon Mill. There are two of them, succeeding each other at a short distance, and they pass through the brickwork at an angle of just 30°. At the gable end of this building there is

another rent in an opposite direction at an angle of exactly 32°. The brick shaft of the mill stands by itself, and is about 40 feet high. The upper part, ten feet from the top, is broken right through, evidently by the swaying motion, and is twisted round on the lower part one inch and a half towards the south-east. The size of the chimney at this part is 3 feet 9 inches square.

In view of Mr. Topley's suggestion that the earthquake may have some connection with the underlying ridge of Palæozoic rocks, it would be interesting to know if any shocks were felt in the Boulonnais and the Ardennes. J. E. TAYLOR

Ipswich Museum

AT the Cross Farm, East Mersea, on April 25, I was shown in the garden two places where water, it was said, spouted up shortly after the shock on the 22nd. They were about ten yards apart on a freshly dug piece of ground on a slight slope, and the woman who lived in the house close by informed me that after the shock she had observed water spouting out from them, and that it continued to do so until after her dinner, which was at one o'clock, when it ceased. There was enough water she said to cause a small stream to run down from each place towards her house, where they formed a puddle; her husband tasted the water and told her it was brackish. There was still evidence of the truth of this statement: the earth at each spot was damp, as was also a small channel which the water had made running down the slope. It appeared as if a small underground water-pipe had burst and the water had been forced above the surface. Cross Farm, I believe, is about a quarter of a mile from the sea, and perhaps twenty feet above its level. EDWARD NEWTON

Lowestoft, May 5

THIS village lies partly on the lowest beds of the Chalk, and partly on the Gault; it is between N. lat. 51° 49′ and 51° 50′, and W. long. 0° 40′ and 0° 41′. The shock was felt at the church, and at two cottages where are invalids in bed. The church is on rising ground at the edge of the chalk platform which lies below the Chilterns, some two miles away from them. I was on the scaffolding erected for repairs to the church. At a little past nine—it could hardly have been later, I think, than 9.15, if so late—I felt the church give what seemed like a fierce shudder. This seemed to begin on the east, rather to north, and travelled westwards nearly. By shudder I mean that a sort of vibration began, which almost instantly increased in intensity, reached a climax, and then rapidly decreased and died away. It seemed to me to begin slightly north of east, because I remember feeling (for what reason I can hardly say) that the cause was hidden from me behind the east end of the church. I was on the south side, some eighteen feet from the south-east corner. A moment after a whirlwind followed, which began, as I find, near the top of the slope north-east of the church, and followed the churchyard wall which bends round the churchyard to south-west. In a cottage on the junction of the Chalk and Gault (or very near the junction), according to the result of inquiries I have made of an invalid there, the pictures on a wall lying north-west and south-east waved from and to the wall, but seemed also to move along it somewhat, *i.e.* north-west and south-east. Flower-pots on a table rocked in a direction almost east and west, and a window facing the south-east shook; her bed also, lying north-west and south-east, waved, and seemed as if giving way. This took place, she says, a little after nine. In a cottage on the Gault where another invalid was lying, a window facing south-west rattled, a picture shook on the wall on which it is fixed, and the bed, lying south-east and north-west, also waved. This was, she thought, at nine, but the time must have been later. She noticed that the wind was still. No noise was heard except the clatter caused by the rattling of the buildings; but at a mill on the Icknield Way, near Tring, lying at nearly lat. 51° 48′, and long. 0° 40′, a rumbling was heard. FREDERICK W. RAGG

Masworth Vicarage, Tring, May 6

Black Rain

THE following paragraph from the *Field* of May 3 will probably interest those of your readers who have seen my note in the last number of NATURE (p. 6):—

"Black Rain.—Yesterday afternoon (April 28) a violent thunderstorm raged over the district between Church Stretton and Much Wenlock. Torrents of rain fell, seemingly a mixture of ink and water in equal proportions. One old man here says he never saw anything like it but once. I certainly never saw such a coloured rain, and I intend to have a bottle of it analysed. Even this afternoon the little brooks are quite black, and the ruts in the roads look as if ink and water had been poured into them.—Rev. R. I. BUDDICOMBE, Ticklerton, Church Stretton."

An analysis of the rain which fell at Stonyhurst showed that the impurity was almost entirely carbon. S. J. PERRY

Stonyhurst Observatory, Whalley, May 4

The Remarkable Sunsets

BECAUSE of the volcanic hypothesis that has been proposed to account for the red sunsets of the past fall and winter, other instances where similar phenomena have been seen after like eruptions are of interest.

Graham's Island, which arose off Sicily in 1831, attracted attention from July 19 to August 16, but was most active on August 7, according to the account given by John Davy in the *Philosophical Transactions* for 1832. The same writer says (p. 252):—"In the month of August a singular appearance was witnessed in the heavens, many evenings successively, both here and in Sicily. Soon after sunset the western sky became of a dark, lurid red, which extended almost to the zenith, and continued gradually diminishing in extent and intensity even beyond the limit of twilight."

A few days after this eruption, August 11 and 12, on the clearing away of a hurricane, the sun appeared blue at the Bermuda Islands (*Amer. Journ. Sci.* xl. p. 323); on August 13, 14, 15, at Mobile, in the southern part of the United States, the rays of the sun were pale blue or violet, varying to sea green (*Amer. Journ. Sci.* xxi. p. 198).

In the month of October the sunsets were prominent enough in the vicinity of Washington to attract popular inquiry. At Alexandria, Virginia, October 12, the heavens continued to reflect a very red light for a long time after the sun had set. October 13, at midday, the sun had a silvery appearance, and its rays gave a ghastly appearance to the countenances of persons. Between 3 and 4 p.m. it appeared greenish blue (*Niles' Register*, October 1831). L. G. CARPENTER

State Agricultural College, Lansing, Michigan, U.S.A., April 17

IT may interest readers of NATURE to learn that on the occasion of a rain-storm at 5 p.m. on the 26th ult. at Crowle, an agricultural village a few miles eastward of this city, the rain-water was so greatly discoloured and loaded with an ash-like matter as to present, until after subsidence, a deep black hue, when caught in vessels placed for the purpose. Again, on Saturday last, the 3rd inst., on the occurrence in this city of rain-storms during a half gale from the north-west, there remained after the storms, on the panes of windows exposed to the north west, a considerable film of dust which had fallen with the rain. While writing it may be mentioned that the phenomenon described as red sunrises and sunsets has prevailed here, before and after sunset, ever since November 9 last; of late, in gradually decreasing tone and variety of colour, and extent of sky area. The coloration at this date is of a russet hue, and there is a steely glare. J. LL. BOZWARD

Worcester, May 5

Rotating Thermometers

IN reference to the Froude thermometer, to which attention is drawn in your last number (p. 6) by Mr. Hazen, I feel confident that if its merits were better known it would be universally employed, not only as insuring among all observers absolute uniformity in the record of the temperature *of the air*, but as affording the only satisfactory means of determining the degree of saturation by means of the wet and dry bulb. Nothing is more perplexing to the meteorologist than the selection of his screen and of an appropriate site. The system of whirling a thermometer rapidly through the air effectually dwarfs all external influences from the rapidity with which renewed particles constantly impinge on the bulb, and it is well known that in the case of the wet bulb the indication is greatly affected by the presence or absence of wind. I found this to be practically the only means of determining the temperature and humidity in a steamer at sea. The only objection was the inconvenience and risk of whirling small thermometers on a string,

and the difficulty of reading without affecting their record; but this I completely got over as explained in my "Visit to South America," 1878, by using a simple whirling table, on which the thermometers were fixed, the reading being effected by bringing them in succession under a plate of glass covering part of the circumference of the table. Nothing can exceed the simplicity of such an arrrangement, which is almost independent of position, and with *small* thermometers affords a uniformity and accuracy impossible of attainment with a fixed thermometer, as it becomes a repeating instrument by a few extra turns of the table, thus insuring freedom from error of observation. I have used this system for many years with most satisfactory results.

EDWIN CLARK

Science and the Public Service

WHILST sincerely regretting the new scheme of openly cutting down the science marks in the army examinations, I think it is not so much the low maximum of marks supposed to be attainable which is discouraging the science subjects, as the low marks actually given at all Government examinations (excepting the Indian Woods and Forests) to any one who is so unwise as to take up natural science. To take, as an example, the Indian Civil Service marks of last year. While in French and German, each of which is a 500 subject, more than 30 per cent. of the candidates obtained over 200 marks; in chemistry, which is also a 500 subject, only two out of thirty-two, or 6 per cent., scored over 200. The marks in the other subjects included in the fatal column of natural science are equally low. Now I do not think that any one will maintain that science is not properly taught at Clifton, Dulwich, &c., yet in French and German a boy has every chance of obtaining 100 marks more than in chemistry (the highest marks last year were—chemistry 229, French 325, German 347). Two possibilities present themselves: either the clever boys will not take up science subjects at all owing to the low marks persistently given, or the examiners expect more chemical knowledge from a boy of eighteen (who must take mathematics or classics, English, &c., in addition to chemistry) than he can possibly acquire. I trust that examiners may be induced to seriously consider the last possibility.

F. C. S.

THE ROYAL CORPS OF NAVAL CONSTRUCTORS

BY an Order in Council of August last this corps was established; an Admiralty Circular of November last published the details of the new arrangements; and the result of the first examination for the grade of "Students in Naval Construction" has recently been announced. An important change has thus been made in the entry, training, and promotion of the professional officers upon whom devolve the responsibilities connected with the design and construction of ships for the Royal Navy; yet little public interest has been evinced. There can be no dispute, of course, as to the great importance attaching to the maintenance in the highest state of efficiency of the constructive department of the navy. Shipbuilding is making such rapid strides that all who have to take part in its developments, whether for war or for commerce, require a highly scientific as well as a thoroughly practical education, if they desire to keep in the forefront of progress. And for modern war-ships with their high speeds, heavy burdens of armour and armament, and liability to damage in action, specially difficult problems continually present themselves, the solution of which is only possible by means of scientific procedure. Recognising these facts, it may be well to make a brief statement respecting the new Constructive Corps, and to indicate the manner in which its creation may be beneficial not merely to the public service but to the mercantile marine.

It is only proper to remark at the outset that the Lords Commissioners of the Admiralty have hitherto been the chief patrons of the scientific education of shipbuilders in England; and to their generosity has been due the existence of the only establishments in which the higher training of naval architects was provided for. Early in the present century (1811) the first School of Naval Architecture was established in Portsmouth Dockyard, and continued at work for more than twenty years. It was established in consequence of the absolute necessity for opposing to the well-trained French naval architects men of equal education and ability, who could not be found at that time in our naval service. Ship-designing was clearly in a very inferior position here, when no shame was felt in building servile imitations of vessels captured from the French. In 1832 this school was abolished, and for sixteen years there was no training establishment of the kind open for English students. But during that interval men educated at Portsmouth occupied important positions both in the Royal Naval service and in private establishments, helping to maintain our national reputation. In 1848 a second school was opened at Portsmouth, on a much more modest scale, and destined to have a shorter life, for it lasted only five years. That brief period sufficed, however, to produce a number of men still holding some of the highest positions in the profession. Another interval of ten years elapsed, and then the Royal School of Naval Architecture was opened at South Kensington, the Admiralty giving it large support, although it aimed at educating other than Admiralty students. Since 1864 there has been no interruption in the good work, although in 1873 the establishment at Kensington was broken up, and the Admiralty section of it transferred to the Royal Naval College at Greenwich. There, as at Kensington, all comers are welcomed if they possess sufficient preliminary training, and private English students, as well as foreigners, have opportunities for instruction afforded them as good as those which the Admiralty provide for their own students. By the munificence of Mrs. John Elder the University of Glasgow has had a Professorship of Naval Architecture recently established, and the classes will, it is understood, commence work this year. But up to the present time the Royal Naval College affords unrivalled opportunities for instruction, and may challenge comparison with any similar institution in Europe.

By means of the very excellent training schools in the Royal dockyards, and the large field of selection from among the apprentices, the Admiralty have been able to secure a continuous supply of well-prepared students for the higher training at Kensington or Greenwich; and thus have obtained the educated naval architects required for the public service. Nor is this all that has been done. A very considerable number of the trained men have passed from Admiralty employment into private establishments, where they have done and are doing good work.

It may be asked, in view of these results, why change a system which has worked so well? The answer is twofold. First, there were grave objections to the continuance of the restrictions imposed by the regulations for first entry into the service. Second, there was not proper recognition of the special training which a student had received when he passed out into actual work, nor any guarantee of a subsequent career. These points require brief explanation.

Although the Admiralty so fully recognised the value of scientific training for its naval architects, and made provision for it, yet for half a century they maintained regulations which necessitated the first entry into the service being made either as an apprentice or as a working man. A few exceptions may be quoted: but the general rule was as stated. The result of this arrangement was that, with few exceptions, candidates for entry came from the working classes; and there was no attraction into the service of the sons of persons in good social positions, such as very commonly become pupils of civil or mechanical engineers. This was obviously a matter which required alteration. The competition for entry was absolutely free, no doubt; but it was surrounded by conditions which

made the real field of selection narrow, and did away with many possibilities of attracting well-educated youths into the service.

Competition was of the essence of the whole system—unlimited and fierce. There was an open competition for entry as apprentice, with probably ten times as many candidates as there were appointments; then from amongst each year's successful candidates—perhaps thirty or forty in number—three only could reach the Naval College after five or six years' work and frequent examinations. Supposing the College course successfully passed, and the student launched on his professional career as a fully certificated naval architect, he then only began a fresh series of competitive examinations on the result of which depended his future promotion. This was a second objection to the old scheme: it was much the same as if a wrangler were called upon to begin work as teacher in an elementary school, and to compete for that position in elementary subjects with men who knew little or nothing beyond those subjects.

Both these objections have been disposed of by the constitution of the Constructive Corps. For the future, while the apprentices in the dockyards will still retain the possibility of advancement to the highest posts, a new class is to be created, termed "Students of Naval Construction." Not more than three are to be entered annually by open competitive examination; they will receive special training at Portsmouth for six years in both professional and educational subjects, living meanwhile in quarters there, and receiving the same treatment as is given to the students in course of training as engineer officers of the Royal Navy. No possible objection need be felt by any gentleman in placing his son under these conditions, and the training is certain to be thorough. Once entered at the Training School, a student has a definite career before him, provided he is well behaved and diligent. He has simply to pass certain standards to insure entrance into the Naval College; and similar conditions hold good during his stay there, as well as at his graduation therefrom. Very properly, powerful inducements are offered to the students in order that they may exert themselves and pass out in the highest class; but those who pass the standard fixed are to receive appointments at once as Assistant Constructors in the Royal Navy. With position thus assured to begin with, and with duties to perform suited to the special training received, the graduates of the Naval College can look forward to an honourable and useful career in the Constructive Corps. Promotion throughout the subsequent stages is to be by selection, and not by competition, selection being governed by the reputations which men make in their professional work.

There are many degrees of rank in the new corps, reaching up from the junior assistant constructors, to constructors, chief constructors, and the highest office—that of Director of Naval Construction, now so worthily filled by Mr. Barnaby. But from the highest to the lowest all the members of the corps have recognised positions in due relation to one another. This is a great gain.

Still another notable feature in the new arrangements is the possibility which now exists for a naval architect who has obtained his training outside the Admiralty service to enter it after he has proved his capabilities for the appointment of assistant constructor by passing a test examination at the Royal Naval College. There are certain limits of age laid down, and it is possible that the number of candidates who will present themselves for some time to come will not be great. At the same time the Admiralty have shown a wise discretion in thus extending the field from which their shipbuilding officers may be recruited. The private trade has drawn largely hitherto from the Admiralty staff: perhaps some return will be made in future.

In the Constructive Corps are included all the principal officers at the Admiralty and in the Royal dockyards, and all the specially educated men from the Naval College who have been successful in their course of study. Provision is also made for admission to the corps of subordinate shipwright officers from the dockyards who may be qualified for the appointment. This is a matter of less public interest than those above mentioned, but it has a very important bearing on the discipline and smooth working of the dockyards.

These are the main features of the new arrangements. They promise well for the future. While retaining for the apprentice class their possibilities of advancement to the highest positions, the Admiralty have greatly enlarged the field of selection for their constructive staff, and made it possible for any gentleman to place his son in the Training School at Portsmouth with the assurance that the surroundings will be as suitable as the system of training is excellent. Further, the Admiralty have recognised the wisdom of training men who from the first shall take rank as officers, and not be compulsorily forced through the grade of workman in order to become officers. This is what is done in all the principal foreign navies and in private establishments: it need not involve any loss of practical knowledge of details, and it is a gain from an administrative point of view.

For my present purpose it will suffice to terminate here this sketch of a "new departure" which promises well for the Royal Navy, and to which most people will wish entire success. There are matters of detail which seem open to criticism, and it would be interesting, did space permit, to show in what respects the new regulations resemble or differ from the corresponding regulations in force in the French or other foreign navies. As this could not be done within the limits of this paper, I have been content to draw attention to the openings which the Admiralty have presented to youths who have a taste for naval architecture, but who would not submit to the drudgery of an ordinary apprenticeship; and have endeavoured to point out how the public service may be benefitted by the changes introduced.

The shipbuilding profession has hitherto been a very "close" one, both in the public service and outside it. But it may be reasonably anticipated that, at least in the Royal Navy and possibly in private establishments also, a change of system would prove advantageous. If the conditions for admission and training are made to resemble more closely those holding good in various branches of engineering, there seems no good reason why a larger number of well-educated and intelligent young men should not adopt naval architecture as a profession. The new Constructive Corps has been created on the recommendation of a departmental Committee, of which Sir Thomas Brassey was chairman. The Report of this Committee, as well as the minutes of the evidence taken by them, have been published as a Parliamentary Paper (No. 277 of 1883), and will well repay perusal. It may there be seen that the appointment of the Committee resulted chiefly from action taken by Admiral Sir Houston Stewart, when Controller of the Navy: and it is a matter of great gratification to myself that I had the honour of assisting that distinguished officer in the preparation of the scheme, which was substantially recommended by the Committee for adoption, and has been adopted by the Admiralty. A few years' experience will decide whether or not the benefits anticipated from the changes above described will be realised. Much must depend, no doubt, upon the manner in which the scheme is developed, and the pocess must be gradual and carefully watched if it is to be successful. But whatever the result may be, nothing but good can come from the changes which enlarge the field of selection for the shipbuilding officers of the Royal Navy, and which unite in one corps all ranks and classes of the constructive staff.

W. H. WHITE

THE FLORA OF PATAGONIA[1]

THIS work, the joint production of the late Prof. Lorentz and of Mr. G. Niederlein, is a substantial addition to our knowledge of the vegetation of one of the least explored portions of the earth. It forms one portion of the scientific results of the expedition into Patagonia conducted in 1879 by General Roca, who has since been elected President of the Argentine Confederation. The Indians who, under the vigorous and stern administration of General Rosas, had been terrified into inaction, if not into submission, gradually took courage when they had to deal with less energetic opponents. At repeated intervals the wandering tribes, especially those of Araucanian stock, made destructive incursions through North Patagonia and the south of the province of Buenos Ayres, massacring the white settlers and driving off the cattle. It had long been the declared policy of the Argentine Government to confine the Indians to the region south of the Rio Negro, by establishing military posts at suitable points in the valley of that river; and to carry out this project was the object of General Roca's expedition. The chief station occupied was Choloechel, a large island inclosed by two arms of the Rio Negro. From thence the upper valley of that river was followed to its junction with a large tributary, the Nauquem. Prof. Lorentz had already returned to Buenos Ayres, while Mr. Niederlein travelled northward to Mendoza. Although the expedition was carried out at an unfavourable season—the autumn and early winter of the southern hemisphere—the authors succeeded in collecting 337 species, of which thirteen are ferns and the remainder flowering plants, in a district which includes only the north-western portion of Patagonia. It is not, however, easy to say how many of the numerous species not hitherto recorded as natives of Patagonia are henceforward to be added to its scanty flora. Many of the species recorded were found in the region lying north of the Rio Colorado, which is generally regarded as the northern boundary of Patagonia, and are not said to spread to the south of that river. Again, as many as sixty-five species of flowering plants were collected in such an imperfect condition that the authors have not been able to assign to them specific names, and many of these will doubtless be found identical with those already known as natives of the country. Further, it must be added that, of twenty plants described as new species, several appear to rest upon slight distinctive characters, which, in the eyes of many experienced botanists, will entitle them to be counted rather as varieties than as altogether new species.

Making due allowance for these deductions, it appears that we may reckon about 150 species as additions to the meagre catalogue of the plants hitherto known as indigenous to Patagonia, scarcely 300 in number for a territory more than 1000 miles in length and from 200 to 400 in breadth. Apart from the interest felt by the systematic botanist in the special forms of vegetation displayed in each region of the earth, many questions of a more general character are suggested by the study of local floras, and that of Patagonia is especially suggestive. Ever since naturalists ceased to regard the existence of each organism as due to a special and separate act of creation, and have learned that the existing population of each region is derived by descent with modification from earlier races, the influence of geological and physical changes has assumed a paramount importance in regard to all changes relating to the geographical distribution of plants and animals. If we seek to understand how the flora of a given region of the earth has come to be what it is, our first business is to inquire into the past history of that region, and to ascertain from what sources the indigenous species may have been derived. With reference to the special features of the Patagonian flora, the subject was discussed during the past winter at a meeting of the Linnean Society. It was then pointed out that nearly the whole of Patagonia and a considerable part of the adjoining Argentine territory had been raised from beneath the sea-level during the latest geological period, and that the only quarters from which the vegetable population could be derived were either the range of the Andes or the subtropical region now included in the northern Argentine provinces. It was argued that the exceptional poverty of the Patagonian flora is not mainly due to climatal conditions, but to the fact that in the time which has elapsed since its upheaval only a relatively small proportion of the plants of the adjoining regions had been modified to suit the conditions of life in the newly-formed territory.

It is interesting to see what light is thrown on the subject by the present work, which, although bearing the date 1881, appears to have but very recently reached this country. Our previous knowledge of the flora was nearly confined to the region near the coast, whereas most of the plants here enumerated come from the territory near the eastern base of the Cordillera. Whether owing to the season, or to the fact that they do not extend to the interior, many of the indigenous species known to occur near the coast—at least a hundred might be enumerated—are absent from the enumeration of MM. Lorentz and Niederlein. But a comparison of all the materials accessible displays a remarkable degree of uniformity in the general features of the vegetation. When raised from the sea the newly-formed territory of Patagonia was dependent for a vegetable population on the immigrant species which it might receive either from the range of the Cordillera to the west, or from the subtropical region to the north. As a matter of fact the predominant features of the vegetation are derived from the lower zone of the Andes, the majority of the species being either the same or slightly modified forms of plants of that zone. Our knowledge of the eastern slopes of the Andes in Patagonia is so imperfect that we cannot say whether a few apparently very distinct plants, two of which are here described as types of new genera under the names *Niederleinia* and *Grisebachiella*, are derived from the higher zone of that range; but it is remarkable that as a general rule very few of the characteristic plants of the higher Andes should have been able to adapt themselves to the conditions of life on the plateaux of Patagonia.

The plants of the subtropical region have exhibited greater power of adaptation to new conditions. Of the larger trees none have been able to spread so far southward; and, except where planted and specially protected, it is not likely that they ever can do so. But of the small bushes and perennial herbs which make up the bulk of the flora a considerable number must be reckoned as more or less modified descendants of subtropical types. It is rather singular to note that this power of adaptation seems to be characteristic of certain groups or natural orders. The most marked instance is that of the *Leguminosæ*. In the Old World the tribes of this family characteristic of the tropics show no tendency to extend into the warm temperate zone, the only exceptions that suggest themselves to the writer being a few acacias in North Africa; whereas we find in this volume out of twenty-one species of indigenous Leguminosæ ten belonging to characteristic genera of the tropics, including two species of *Cæsalpinia* and one (new) species of *Mimosa*.

The condition of an extensive territory inhabited by a relatively small number of indigenous species, many of them probably but imperfectly adapted to their environment, was evidently very favourable for colonisation by new immigrants; and the chances in favour of the new comers were further increased on the introduction of agriculture and of domestic cattle from the Old World. The plough clears the ground from many bushes and

[1] "Informe Official de la Comision Cientifica agregada al Estado Mayor General de la Expedicion al Rio Negro (Patagonia) bajo las ordenes del General D. Julio A. Roca." Entrega II. Botanica. (Buenos Aires, 1881.)

perennial herbs, and cattle make war on the species suitable for their food, and at the same time carry with them the seeds of many species adapted to such means of transport. To these causes we must attribute the wide diffusion of many plants, chiefly from southern Europe, introduced by man, either accidentally or intentionally, into the Argentine region and North Patagonia. A few of these appear, to have spread beyond the bounds of European colonisation, but the majority seem to keep pace with the extension of the white race and of domestic cattle.

This volume, dated 1881 when it went to press, but not published till 1882, is very well printed and illustrated by twelve well-executed lithograph plates, in a manner creditable to the typographic resources of Buenos Ayres, and reflects honour on the administration of the republic and on General Roca, who, as commander of the expedition, deserves the credit of associating with his staff several competent scientific men. We probably owe it mainly to his influence that the results have been given to the world in a manner so complete and satisfactory.

J. B.

ACROSS THE PAMPAS AND AMONG THE ANDES[1]

THE interest attaching to the confederation of South American provinces known as the Argentine Republic more than justifies Prof. R. Crawford in the publication of an account of his journeys across the Pampas and the Andes. Some fourteen years ago the Government of the Province of Buenos Ayres, foreseeing the vast importance of a line of railway which would connect the two oceans, entered into an agreement with the firm of Waring Brothers of London to send out a staff of engineers to explore and survey a route for a proposed Transandine railroad. Prof. R. Crawford was given the command, and, with his colleagues, left Liverpool in March 1871 for Monte Video, which was reached after a voyage of a month's duration. On landing, it was soon ascertained that matters were in desperate plight at Buenos Ayres. The frightful epidemic of yellow fever was still raging, the local Government had proclaimed public holidays and itself migrated to a distance from the doomed city, business of all sorts was suspended, and silence reigned in the streets. Under these circumstances, but for the pluck and energy of Prof. Crawford, the scheme for the survey across the Pampas would have come to an untimely end (that from the Chili side had commenced towards the end of April 1871); but he determined it should proceed, and never let the local authorities have any rest until all preliminaries were settled. In the meanwhile the enforced sojourn at Monte Video was not over pleasant. The city was in a state of siege, and it was not for some time after the arrival of the party that a temporary peace was patched up. Weary of the forced delay, Prof. Crawford and some members of his party visited Concordia and made a survey for the Salto Grande Canal. They passed, in their voyage up the Plate, Buenos Ayres, looking in the distance bright and pleasant, though death was stalking through it. In steaming up the Uruguay they saw Liebig's famed extract-of-beef factory at Fray Bentos, and McCall's vast establishment at Paysandu. In an account of a short excursion made from Concordia, we find the following interesting anecdote about the black vulture (*Cathartes atratus*) of La Plata; perhaps the coolness of the vulture's behaviour is fully equalled by the coolness of the driver in appropriating the stray horse:—

"The roads were very sandy, and the wheels sank deeply into them, making the carriage heavy to draw, so that the driver gladly appropriated a stray horse we met upon the way that seemed inclined to join himself to ours, and having extemporised a rude set of harness with some spare pieces carried in reserve, attached him to our team, and drove off in triumph with this new acquisition.

"I was sitting on the box-seat with my gun in hand, when a black vulture came flying past, at which I fired, bringing it to the ground with a broken wing. The strange horse testified his dissatisfaction with the proceeding by the most violent plunging and kicking, that required all the driver's skill and address to overcome.

"When at last he was brought to a state of rest, due, no doubt, in a great measure to exhaustion, the wounded bird occupied our attention by the strange coolness of its proceedings. Regardless alike of our presence and an injured wing, to say nothing of the noise and confusion the horse had created, instead of attempting to escape, it walked quietly up to us, as if about to demand an explanation of the treatment it had received; then mounting deliberately on the wheel of the carriage, hopped in through the open window as composedly as if it were a regular passenger about to occupy an inside seat for which it had been booked in the ordinary manner.

"So offensive was the odour emitted by the unwelcome intruder that we could with difficulty bring ourselves to approach and dislodge it; and when we had done this, the vulture took refuge under the legs of the strange horse, frightening him to such a degree that he began again his strenuous endeavours to get loose, not stopping till he succeeded in smashing the harness to pieces, and escaping from his flapping foe.

"I am afraid that I was not popular that afternoon with my comrades and the driver, for my unlucky shot had entailed upon them much inconvenience and delay, so that it was late when we reached the estancia house."

Just as the survey of the canal was finished, traffic between Monte Video and Buenos Ayres was resumed, and, returning to the former place, the whole expedition left for Buenos Ayres on June 16, 1871. The city was still overwhelmed with gloom. Between 20,000 and 30,000 of its inhabitants had been buried within the few previous months out of a population of only 200,000 souls. Numerous houses had the plague spot still marked upon them, but in a very short time things looked more cheerful, and there were no outward tokens of the plague the city had passed through. Now began the negotiations for the necessary escort to accompany the expedition across the Pampas. While the expenses of the expedition were in great measure to be defrayed by the local Government of Buenos Ayres, it will be remembered that this Government has no national authority, nor could it undertake any outside its own territory, it was therefore necessary for the provincial Government to come to an understanding, which they did, with the national Government and with its neighbouring provinces, and with the Republic of Chili, for the passage of the expedition through these lands and for the supply of a military escort. "Along the whole route," the general commanding on the frontier reports to the President of the Republic (May 20, 1871), "there will be danger: the Indians were in a state of alarm that the objects of the Survey were to take more and more of their territories from them, and were determined to destroy the members of the expedition when possible," and the general calculated that an adequate force to properly protect the party from all danger should not number less than 1500 men perfectly equipped. Under these circumstances, and after some months' delay, the originally proposed route was abandoned, and a more northern one, in territory likely to be more free from the predatory attacks of the Indians, was adopted, and with a small escort the expedition left Buenos Ayres on August 17, 1871, and took up their quarters at Chivilcoy, 100 miles to the west of it; here final preparations were made for the formidable journey across the Pampas. The Chili expedition in the meantime had, before reaching the summit of the mountains,

[1] "Across the Pampas and the Andes." By Robert Crawford, M.A. With a Map and Illustrations. (London: Longmans, Green, and Co., 188 .)

been obliged, owing to heavy falls of snow, to abandon the work, which was not resumed until September. In this month too the preliminary party of the Pampas expedition started, and were followed by the rest of the party towards the end of October. We leave the reader to peruse in the volume itself an account of all the troubles and difficulties that had to be, and were, overcome ere a party of sixty-six persons, not counting the escort, could be started on such a journey across the boundless Pampas.

By the end of November the Indian frontier was reached, the work of the Survey having proceeded well. Water was often scarce, and only procured by sinking wells, which furnished but very moderate supplies. Some very sudden changes of temperature were encountered. Thus, on November 13, "the thermometer, which had hitherto been registering great heats, suddenly fell to 26° F., converting the water in our tents into ice." Deer (*Cervus campestris*) and partridge (*Nothura maculosa* and *Rhyncotus rufescens*) were abundant. The deer at the season they were met with went about in small herds of from three to seven. As they advanced water became more scarce, and moreover was often muddy. Once when the stock at the disposal of the engineers' mess was reduced to a small kettle-full, and that heavily charged with sediment, it was resolved as a means both of economising the fluid and making the most of the mud, that it should be made into coffee. Anxiously the little group sat around the camp fire watching the kettle, the water in which was never to boil, for by some unfortunate accident, the particulars of which were never explained, as the subject was one too painful to be talked over, the kettle was overset, and its contents poured out on the resenting flames, amidst a groan of horror from the parched throats around it. In this Indian territory Rheas (*Struthio rhea*) were numerous, and the young birds were very easily tamed, those captured by the men becoming pets in a few days, and wandering about the camp like young turkeys. The

Tupungato, from the River Lujan.

generally careful and prudent engineer-in-chief was here on one occasion so heedless of his own safety that he was nearly coming to grief. One night he passed out of bounds unnoticed, but on attempting to regain the encampment he found his situation most serious, for he was at once challenged by the sentry, who happened to be a Frenchman fresh from the experiences of the Franco-German war, and not being satisfied with Prof. Crawford's explanation, he proceeded to present his rifle. Not anxious to serve as a target, the professor, to prevent the sentry from getting him projected on the sky line, fell flat on the ground, and while in that somewhat undignified position, some of the men coming out on hearing the alarm, recognised his voice, and released him, resolving to be more prudent the next time that he wandered beyond range. Several troops of wild horses were met with; they had all flowing manes, and tails that swept the ground. On November 29, an attack in force of the Indians being most imminent, and the military escort being ordered to retire on Fort Media Luna, the surveying operations were most reluctantly discontinued. The last peg was driven well into the ground and covered with a large mound of earth. When thinking of resuming operations, Prof. Crawford demanded an escort of 200 men, but after a promise of fifty, was only eventually furnished with twenty. To continue the survey work with such an escort was quite out of all reason, and the question arose, what was to be done? After all that had been endured and all that had been accomplished, was the expedition to be abandoned? Such a termination would have been a most painful one to all engaged; Crawford therefore determined to risk everything, and endeavour to accomplish the mission by crossing the Pampas in a compact body, keeping along the line of frontier until the Andes were approached, and then bearing southwards, to ascend their eastern slopes until they should join their colleagues from the Chilian side at the place of rendezvous. This determination they proceeded to carry out on December 6, when Media Luna was left. On the 18th the swampy district known as the "Amarga" was reached

Here the Rio Quinto loses itself in an extensive sandy plain to reappear not far off as the Salado, which river falls into the Plate, about sixty miles south of Buenos Ayres. A couple of days later, near Fort "Nichochæa" [illegible] was met with and the potato in blossom. The tubers of the latter were very small, and, when boiled, tasteless. Lakes were now often met with, the water generally sweet, and the lakes encircled by sand-hills. At Fort Sarmiento the Rio Quinto was crossed; it had here cut for itself a channel 300 feet wide through a gravelly soil to a depth of some ten feet below its banks. About December 23 trees became numerous, and the monotony of the ocean-like plain was broken by the appearance of a mountain (El Morro). Here Colonel Roca was in command of a garrison, and at once struck Prof. Crawford as a man most highly gifted by the possession of many qualities not often associated in the same individual. He has since risen in his profession to be a general, and now as President of the Argentine Republic directs its affairs with wisdom and firmness.

The country now became more interesting, and the Rio Quinto presented well-wooded banks. Christmas Day was spent in camp, the thermometer indicating 104° F. in the shade. At Villa Mercedes the Rio Quinto runs in a valley it has formed for itself some 1270 yards wide. Here oxen were changed for mules, and the weariness of the delay at this station was aggravated by the great heat of the weather during the day, and the intensity, by contrast, of the cold at night, the thermometer ranging from 107° F. in the shade during the day to 34° F. at night. The mules gave great trouble, refusing to carry the baggage carts, and almost bringing the expedition to a close; but again the energy of its head succeeded in getting matters to rights, but not before a journey to San Luis, and procuring there the requisite number of pack mules. San Luis was left on February 3, and Mendoza was reached about the 11th. The first sight of the glorious range of the Andes inspired the expedition with a fresh energy.

"The scene which met our tired eyes was one of such magnificence and grandeur as soon dispelled all weariness, and filled us with wonder and amazement. There stood the Andes boldly outlined against the sky, with the mighty 'Tupungato' towering like a giant above the other peaks, its snow-clad summit bathed in gold by the sun's first rays (itself not yet apparent over the horizon), while rosy clouds alternating with crimson and violet of deepest hue, brought out the lights and shades upon the rugged mountain tops, and all below was merged in one vast sea of sombre grey, night's mantle, which the sleeping earth had not yet put aside. Each moment did the picture alter, and every change brought with it some fresh beauty not before perceived, till the sun, rising from the pampas as from the ocean, covered the mountains with a dazzling light, in which the delicate tints and shades of colour disappeared, and last of all the darkness at their base resolved itself into a thin blue cloud like smoke, which hung about them for a while, and then too, was in turn forced to yield and vanish as the rest had done. It was impossible to look on such a scene unmoved, or to find words wherewith to reproduce it to another's eye. Gladly would we have lingered gazing at the view before us, but business, demanding our attention, recalled us to more practical affairs. It was necessary that we should be off without delay; a long and weary journey lying before us. That day we travelled six-and-thirty miles, three-fourths of the distance being over a barren sandy soil, destitute alike of grass and water. The day was very hot, and during it all our dogs, which for many months had followed the fortunes of the expedition, disappeared; where they had gone to no one knew, but it was thought that possibly they had sought shelter from the scorching heat under some thick shrubs we passed upon the route, and never afterwards had been able to overtake or find us; or when the cold of night came on, they may have retraced their steps back on the route we took that morning and joined their lot with the first settler they fell in with. Whatever was their fate, we deeply regretted to have lost our faithful followers and friends."

Soon they were up among the Andes into deep ravines among lofty hills, now descending into valleys, and soon afterwards ascending giddy heights. An extinct volcano, now a beautiful mountain called the "Cerrito Diamante," was passed; some thirty miles from it a rill of a yellowish-white fluid, like petroleum, issuing from the mountain-side at a considerable height, was discovered. The source from which it flowed was at the junction where a hard metamorphic rock interspersed with small augite crystals overlay a stratum of volcanic tuff. It was in form like a crater of a volcano, and full of a black bituminous matter, hot and sticky, which could be stirred to a depth of about 18 inches. Floundering in it was a polecat, which had been enticed to its fate by a bird caught in this natural birdlime. The overflow was 2 or 3 feet wide, and as it spread out it became of an asphalt-like form. Two other little birds were found entangled in the stream, and on being released both feathers and skin came off. Possibly they had mistaken the stream for water. A further search revealed many bird and small mammalian skeletons embedded in the mass, possibly a puzzle for some palæontologist in days to come. After leaving the River Atuel sandstone and limestone strata were met with, and on February 29 their colleagues from the Pacific coast who had crossed the Andes by the Planchon Pass were met. The combined party rested a few days in the highland valley of Las Leñas Amarillas, where guanacos abounded. The watershed of this district was reached at a level of 9200 feet above the sea, the scenery being of surpassing beauty, and the Andes are described as having no lovelier spot than this secluded "Valle Hermoso." Here a good deal of land-surveying was accomplished, and also in the region of the Rio Grande. In the middle of March the passage of the Andes was begun *viâ* the Planchon Pass. The attempt to cross by the head of the Rio Grande was frustrated by the dangerous illness of a colleague when a height of about 11,000 feet had been attained, and fearing the consequences if they bore him to the summit (1000 feet higher), they retraced their steps and went over by the Planchon Pass, 8225 feet above sea-level. On the descent silver and copper mines were passed. After five months of hardships, a day at the lovely baths of Cauquenes was thoroughly enjoyed, and on March 25 the party arrived at Santiago de Chili, described as a city which for its position cannot be surpassed in grandeur and the magnificence of its surroundings. After a fortnight's sojourn here, Valparaiso was reached by rail, from whence, proceeding through the Magellan Straits, Monte Video was reached, and thence home.

All through the narrative the reader's interest is sustained, and the author might often indeed have ventured on further details without the least risk of being tedious. The trials and hardships undergone are very slightly dwelt upon, but they must have been many and great. On the result of his labours, and on this pleasant narration of some of the chief incidents of his travels, we heartily congratulate Mr Crawford, whom we are also glad to find once more located within the walls of his ancient University, laying the varied experiences of his life before the engineering classes of Trinity College, Dublin.

In a most valuable and important series of appendixes we have an excellent account of the peaks and passes of the Andes, which seem in every way worthy of the Alpine clubs of Europe; a most important essay on the Argentine Republic, its position and extent, its Indian frontier and invasions, its colonies and railways—a Republic with a great future before it, and one in which our British interests are largely involved.

THE INTERNATIONAL HEALTH AND EDUCATION EXHIBITION

THERE is at first sight some lack of unity of purpose in an exhibition which undertakes to illustrate such diverse subjects as health and public education. This impression will be in the present case confirmed partly by the postponement of the opening of the Educational Section to the month of June, and partly by the fact that the display of educational appliances will be held in the neighbouring building, the new Technical School of the City and Guilds of London Institute, and not in the galleries of the Exhibition building itself. A mere miscellaneous collection of objects more or less illustrative of school work, *e.g.* furniture, fittings, apparatus, and diagrams, would, however, prove of little general interest and value, unless it were on a very comprehensive scale. The Executive Committee, therefore, have wisely decided to limit the scope of the educational part of the Exhibition of the present year, and to direct the attention of exhibitors mainly to the elucidation of a few special problems which possess exceptional importance or public interest at the present time. Foremost among these are the subjects of technical and scientific instruction, trade and apprenticeship schools, the teaching of art, and the Kindergarten with other devices for infant training. The accidental association of this part of the Exhibition with one devoted to the subject of health has also naturally suggested another class of illustrative display likely to prove particularly interesting to school managers and the public at this moment. While the Executive Committee has shown no disposition to encourage the absurdly exaggerated and not very sincere outcry which has been raised about the "over-pressure" of children in schools, they have shown much judgment in giving special prominence to those "exhibits" which are designed to illustrate the conditions of healthy life in schools. Accordingly, models of the best school buildings, appliances for warming, lighting, and ventilating, improved desks and fittings, contrivances for securing right posture for the limbs and for preventing injury to eyesight, precautions against disease in schools, will be largely shown. The whole subject of physical training will also, it is expected, be illustrated with unusual fullness and variety. Models and examples of the latest and best forms of gymnastic apparatus in use in England and in foreign countries will be shown; and arrangements are being made, with the sanction of the heads of the Admiralty and of the War Office, for the practical exposition of the methods of military drill in use in the great military and naval schools at Chelsea and Greenwich, on certain afternoons on which the boys can be spared for this purpose from their ordinary school duties.

The increased attention now being directed to the whole subject of infant training; the extended interest taken by the best teachers in the study of the methods of Fröbel; and the recognition by the Education Department for the first time, in Mr. Mundella's Code, of the need of training, object lessons, recreation, and varied employment in infant schools, as well as instruction in reading, writing, and arithmetic, have justified the appropriation of a considerable space to the Kindergarten, and to the exhibition of pictures, games, manual exercises, and apparatus specially adapted for the training of very young children, whether in schools or nurseries. There is reason to believe that this department of the display will be especially full and interesting, and will comprise some of the latest and most ingenious of the devices for infant discipline which are in use in Germany and Switzerland, as well as in our own country.

Closely connected also with the general design of the Exhibition to show how school-life may be made healthier, brighter, happier, and more interesting, there will be a considerable display of pictures and school decorations. The "Art for Schools Association" and other exhibitors will seek to show how the school-room may be incidentally useful in improving the taste and stimulating the imagination of the scholars; and it may be hoped that many teachers will gather from the Exhibition some fruitful suggestions as to the manner in which art may give added reality and force to lessons on history, on descriptive geography, on the facts of science, and on the life of the ancient world.

The London, Birmingham, and other School Boards have arranged for collective displays of their best fittings, desks, and other apparatus. Illustrations and models of school kitchens, cookery schools, and the latest appliances for the practical teaching of domestic economy will be tolerably numerous; and special pains have been taken by those members of the Education Committee who have recently served on the Technical Instruction Commission to procure some of the most characteristic illustrations of the methods of technical and industrial teaching in use in the trade and apprentice schools of the Continent.

There will be a library and reading room attached to the educational department of the Exhibition; and a large collection of the newest text-books, treatises, diagrams, and works of reference having relation to the subject of the Exhibition will be so arranged that they may easily be consulted by visitors.

One very interesting feature of the whole programme will be found in the plan—not yet fully matured—for an International Congress or series of Conferences to be held in connection with the Exhibition during the first week in August. A large attendance of delegates from foreign countries is expected, and some of the most important educational problems of the day will be discussed. The sub-Committee, which has spent much time in arranging the details, is representative in its character, and consists of Lord Reay, the Hon. L. Stanley, two of the Senior Inspectors of Schools, Mr. Sharpe and Mr. J. G. Fitch, Archdeacon Emery, the Rev. Dr. Graham of the Hammersmith Training College, Mr. Storr, Mr. Magnus, Mr. St. John Ackers, and Dr. Rigg. So far as the arrangements have yet been published, they promise to provide a series of valuable public discussions, by persons of authority in their special departments, on the organisation of primary, secondary, and university education; on the conditions of health and physical development in schools; on the professional training of teachers, the testing of their qualifications, and the public recognition of those qualifications; on several special departments of instruction, *e.g.* infant training, art teaching, science and technical teaching; and on museums, libraries, and other subsidiary agencies by which the influence of the school may be extended to the home life, to leisure, and to the means of self-improvement.

NOTES

THE Council of the Royal Society have selected the following fifteen candidates to be recommended for election at the annual meeting on June 12 next:—Prof. George Johnston Allman, LL.D., Prof. Isaac Bayley Balfour, D.Sc., Joseph Baxendell, F.R.A.S., James Bell, F.I.C., Prof. Walter Noel Hartley, F.R.S.E., Prof. Alexander Stewart Herschel, M.A., Wilfrid H. Hudleston, M.A., Prof. Horace Lamb, M.A., Prof. John G. McKendrick, M.D., Arthur Ransome, M.D., Prof. Charles Smart Roy, M.D., Prof. Arthur William Rücker, M.A., Joseph John Thomson, B.A., Lieut.-Col. Charles Warren, C.M.G., and Prof. Morrison Watson, M.D.

THE following three *savants* were elected Foreign Members of the Linnean Society at the last meeting, May 1:—Dr. Ernst Haeckel, Professor of Zoology and Director of the Zoological Institut, Museum, University of Jena, among other things well known for his studies of Sponges, Radiolarians, Medusæ, &c.;

Dr. Alexander Kowalevsky, Professor and Director of the Zootomical Cabinet, &c., in the University of Odessa, notable for his anatomical and embryological researches on the Tunicates, Holothurians, Cœlenterata, &c.; and Dr. S. Schwendener, Professor of Botany, University of Berlin, whose labours in cryptogamic botany, more especially Lichens and Algæ, receive due appreciation by his kindred workers on these and allied topics.

A CIRCULAR signed by Prof. Ray Lankester, Secretary *pro tem.*, and Mr. Frank Crisp, Treasurer *pro tem.*, has been issued from Burlington House, London, with reference to the proposed "Marine Biological Association of the United Kingdom." The object of the Society, as explained by the speeches made at the meeting of March 31, is to erect and maintain at suitable points on the coast one or more laboratories similar to the Zoological Station of Naples and the American Laboratories of Newport and Chesapeake, to which naturalists may resort for the purpose of investigating the history of marine life, both animal and vegetable, and the various conditions affecting the welfare of British food-fishes and mollusks. It is proposed, in the first place, to establish a laboratory on the south coast of England. To build this laboratory and equip it in an efficient manner with boats, dredging apparatus, and tanks, a sum of not less than 10,000*l.* is desirable, whilst an income of not less than 1500*l.* a year will be required to maintain it and to pay the wages of attendants and fishermen and the salary of a resident superintendent. The Provisional Committee, as authorised by the meeting on March 31, has made the following rules with regard to membership of the Society:—"The Members of the Society shall consist of three classes—(*a*) Donors of 500*l.* and upwards to the Society, who shall be Governors and permanent Members of the Council. (*b*) Donors of 100*l.* to the Society, who shall be Founders and Members of the Society for life. (*c*) Annual Subscribers of 1*l.* 1*s.* The subscription may be compounded for at any time by a payment of 15*l.* 15*s.*" The members of the Society will shortly meet to elect a Council and Officers, and to adopt a constitution and rules. It is proposed that the members shall meet at least once a year for the purpose of electing a Council and transacting other business, and they will receive reports of the work done by the Society, and especially of the investigations carried out in the laboratory maintained by its agency. In addition to the fixed contributions above mentioned in connection with membership, the Committee invite special donations towards defraying the expenses of erecting the first laboratory. Those desiring to become members should communicate as soon as possible with the Treasurer, at 6, Old Jewry, E.C.

THE Annual Meeting of the Academy of Sciences of Paris was held on Monday, M. Blanchard, president for 1883, being in the chair. M. Blanchard opened the sitting by an address, reciting all the losses that the Academy had sustained during the past year. He dwelt principally on the exceptional eminence of M. Dumas. He summarised also the several scientific expeditions which had been fitted out by the French Government during the year after having taken the advice of the French Academy. M. Bouley read the list of the awards granted by the several academical commissions, and which is too long to be reproduced in our columns, the number of these foundations being yearly enlarged; thus far no less than three prizes were distributed for the first time—the Penaud Prize for progress in Aëronautics to MM. Tissandier, Taton, and Leroy de Brognac, and two prizes by Le Petit d'Ormay, one for physical sciences, and the other for mathematics. The interest of the Bréant Prize (4000*l.*) for curing the cholera was bestowed on M. Pasteur's pupils, who have studied the subject in Egypt on the spot. One of the astronomical prizes was given to M. Stephan of Marseilles, and the other to several members of the transit missions not belonging to the Academy Gold medals were distributed to the marine officers who took part in the expedition of the *Travailleur* under Milne-Edwards for exploring the Atlantic, and to those who wintered with the *Romanche* in Terra del Fuego, in connection with other Polar expeditions. M. Bertrand read the *éloge* which had been written by M. Dumas on the brothers Deville, both of them members of the Academy of Sciences, who died, Charles, the geologist, in 1876, and Henry in 1881, both at the same age. After having read this address on behalf of his illustrious colleague, M. Bertrand read for himself an *éloge* on Puiseux, a Member of the Mathematical Section.

THE following, according to *Science*, is a complete list of the papers read at the meeting of the United States National Academy of Sciences, April 15 to 18:—G. K. Gilbert, the sufficiency of terrestrial rotation to deflect river-courses; T. Sterry Hunt, the origin of crystalline rocks; Simon Newcomb, on the photographs of the transit of Venus taken at the Lick Observatory; A. E. Verrill, zoological results of the deep-sea dredging expedition of the U.S. Fish Commission steamer *Albatross;* Ira Remsen, the quantitative estimation of carbon in ordinary phosphorus; reduction of halogen derivatives of carbon compounds; Elias Loomis, reduction of barometric observations to sea-level; C. S. Peirce, the study of comparative biography; C. S. Peirce and J. Jastrow (by invitation), whether there is a minimum perceptible difference of sensation; S. P. Langley, the character of the heat radiated from the soil; J. E. Hilgard, on the depth of the western part of the Atlantic Ocean and Gulf of Mexico, with an exhibition of a relief model; on the relative levels of the western part of the Atlantic Ocean and Gulf of Mexico with respect to the Gulf Stream; account of some recent pendulum experiments in different parts of the world, made in connection with the U.S. Coast and Geodetic Survey; E. D. Cope, on the structure and affinities of Didymodus, a still living genus of sharks of the Carboniferous period; on the North American species of mastodon; Theo. Gill and John A. Ryder (by invitation), the characteristics of the lyomerous fishes; on the classification of the apodal fishes; Theo. Gill, on the ichthyological peculiarities of the bassalian realm; George F. Barker, on the Fritts selenium cell; on a lantern voltmeter; George J. Brush, on the occurrence of mercury in native silver from Lake Superior; H. A. Rowland, progress in making a new photograph of the spectrum; B. Silliman, on the existence of tin ore in the older rocks of the Blue Ridge; H. M. Paul (by invitation), the Krakatoa atmospheric waves, and the question of a connection between barometric pressure and atmospheric electricity; John S. Billings, memorandum on composite photographs in craniology; A. W. Wright, some experiments upon the spectra of oxygen; Elliott Coues, on the application of trinomial nomenclature to zoology; E. M. Gallaudet (by invitation), some recent results of the oral and aural teaching of the deaf, under the combined system; F. W. Clarke (by invitation), jade implements from Alaska; Henry L. Abbot, recent progress in electrical fuses; J. S. Diller (by invitation), the volcanic sand which fell at Unalashka, October 20, 1883, and some considerations concerning its composition. The following biographical notices of deceased members were also read:—Of Gen. G. K. Warren, by H. L. Abbot; of Prof. Stephen Alexander, by C. A. Young; of Dr. J. Lawrence Smith, by B. Silliman; and of Dr. John L. LeConte, by S. H. Scudder.

ON Saturday last a banquet was given by a number of anthropologists to M. Gabriel de Mortillet, Conservator of the St. Germain Museum of National Antiquities, and his portrait, was presented to him. M. de Mortillet stated that his usual summer excursion would take place this month or in the beginning of June, and that Brittany would be chosen as a field for exploration. Any person wishing to join the Professor

in his scientific tour may write to M. de Mortillet at the Château de Saint Germain. The banquet hall was decorated with a life-size picture of an early Gaul. The picture was executed according to the last discoveries of M. de Mortillet. The man is represented as having no hair on his body; his arms are very long and muscles very powerful, but the toes of his feet are not opposable, although they could be used for climbing the trees of the primitive forest. His jaw is strongly prognathous, but not at all equal to that of an anthropoid ape. His breadth is strongly compressed laterally and his abdomen prominent. The skin is not negroid, but of our present colour. The expression of the face is in intelligence on a level with that of an Australian.

ANTHROPOLOGY plays a great part in the Paris *salon* this year. One of the largest pictures, attracting the attention of crowds, represents a primæval tribe preparing in their cave to feed upon an *Ursus speleucus* which has been killed by the warriors with their stone implements.

THE spring meeting of the Institution of Mechanical Engineers was held at the Institution of Civil Engineers on May 1 and 2. The most interesting paper read was on the Consumption of Fuel in Locomotives, by M. Georges Marié, Engineer to the Paris and Lyons Railways. This paper is of considerable importance as bearing on the actual economy of the locomotive considered as a heat engine. The chief conclusion is that the locomotive is a better engine, as regards economy of fuel, than is usually believed, and cannot be very much improved unless the pressure in the boiler can be increased at one end or a condenser applied at the other. The author looks forward confidently to both these improvements, but when achieved they will, he considers, necessitate an improvement in the valve gear, and probably the use of compound engines on the scheme now brought forward by Mr. Webb. With these and with some other improvements, such as a better clothing of the boiler and the heating of the feed-water by the exhaust-steam, M. Marié looks forward to the locomotive attaining a position, as regards economy of fuel, much beyond even that which it possesses at present. The other papers read were entirely of a practical character, with the exception of one by Mr. Robert Gordon, of Burmah, describing the apparatus used at Mr. Froude's works at Torquay, for testing current meters. The arrangement of the tank, dynamometer, governor, &c., is clearly described, but would hardly be intelligible without the aid of drawings.

WE are glad to direct the attention of our readers to the *Heal h Journal*, published by Heywood of Manchester, and which, with the May number, has concluded its first volume. The *Journal* is a monthly review "of sanitary science and of voluntary effort for the public good." It seems to us to be admirably calculated to serve the purpose for which it has been established, and we hope it will receive all the encouragement it deserves.

THE recent threat of certain French journals that their troops would occupy the island of Hainan until China had paid an indemnity has directed attention to that little-known appendage of the Chinese Empire. In a late number of that valuable periodical, the *China Review*, we find an account of a journey through Hainan by Mr. Henry. As in other outlying possessions of China, the native tribes have succeeded in a measure in holding their own against the ubiquitous Chinese. The northern part of the island is described as a large plain, while the central and southern portions are mountainous. Here the aboriginal tribes, the Les, take refuge. They are cordial and hospitable to strangers, and are probably of Malay origin. There are fifteen or sixteen different tribes, known under distinct names, varying more or less in dress, language, and customs, but all evidently belonging to one homogeneous race, bound together by common ties, and, as a rule, living on friendly terms with each other. The flora and fauna appear singularly rich, and but little investigated. In a visit of a few weeks the late Mr. Swinhoe noted 172 species of birds, nineteen of which were new to science, and were first described by him. The leeches are an especial plague to the traveller. They are described as of a grayish-brown and earthen hue, and vary from half an inch to an inch and a half in length, and swarm from the ground on all sides. Along the path, on the ends of grass blades and branches of shrubs, they may be seen holding by one end, while they reach out their whole length feeling on every side for their prey. The instant they touch foot or hand, or any part of the body, they take fast hold, and can only be detached by the application of fire, or when they are sated with blood. The natives carry bamboo sticks, with which by a quick motion they can sometimes detach them. Although the people appear in a state of rural prosperity, as there is very little foreign trade, while the climate is bad, it is difficult to see what France would gain by the occupation of the island.

REPORTS from Mount Hamilton, California, *Science* states, say that this has been the most stormy winter known since observations were begun at the Lick Observatory. The bad weather did not begin till so late in January that a drought in California was feared; but there have been 40 inches of rain and melted snow up to April 4, and at that date the mountain was covered with 2 feet of snow. The anemometer cups were blown away, with the wind-gauge indicating 65 miles per hour. The lowest temperature has been + 12°; and at this temperature outside water did not freeze within the uncompleted buildings.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* ♀) from India, presented by Miss Harbord; a Pig-tailed Monkey (*Macacus nemestrinus*) from Java, presented by Miss Ethel Fenwick; a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mr. F. Harrison; a Garnett's Galago (*Galago garnetti* ♂) from Eastern Africa, presented by Lieut. James Knowles, R.N.; a Dow's Tapir (*Tapirus dowii* ♂) from Venezuela, presented by Mr. Reginald Pringle; a Spotted Ichneumon (*Herpestes nepalensis*) from Nepal, presented by Mr. John Walker; two Clapperton's Francolins (*Francolinus clappertoni*) from West Africa, presented by Major H. Wade Dalton; two Chukar Partridges (*Caccabis chukar*) from North-West India, presented by Lieut.-Col. C. Swinhoe; a Herring Gull (*Larus argentatus*), European, presented by Miss Laura Dunnage; two Barn Owls (*Strix flammea*), British, presented by Mr. R. Church; two Hoary Snakes (*Coronella cana*) from South Africa, presented by Mr. E. Watson; two Wattled Cranes (*Grus carunculata*) from South Africa, two Spur-winged Geese (*Plectropterus gambensis*), four Vinaceous Turtle Doves (*Turtur vinaceus*), three Harlequin Quails (*Coturnix histrionica* ♂ ♂ ♀) from West Africa, deposited; a Grey-cheeked Mangabey (*Cercocebus albigena* ♂) from West Africa, two White Cranes (*Grus leucogeranos*) from India, a Cabot's Horned Tragopan (*Ceriornis caboti* ♂) from China, a Banded Gymnogene (*Polyboroides typicus*) from Africa, two Yucatan Blue Jays (*Cyanocitta yucatanica*) from Yucatan, two Axolotls (*Siredon mexicanus*) from Mexico, purchased; a Moustache Monkey (*Cercopithecus cephus*) from West Africa, received in exchange; a Maholi Galago (*Galago maholi*), seven Coypus (*Myopotamus coypus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

WHITE SPOTS UPON VENUS.—Four years since M. Trouvelot drew attention to two remarkable white spots which he had observed on opposite limbs of Venus, near the extremity of the cusps, from November 13, 1877, to February 7, 1878. The

southern spot was the brighter of the two, and "appeared then to be composed of a multitude of bright peaks, forming on its northern border a row of brilliant, star-like dots of light." The white spots disappeared after the inferior conjunction, which occurred on February 21.

At the sitting of the Academy of Sciences of Paris on March 24, M. Trouvelot mentioned that on two hundred and forty-two occasions since February 1878 he had observed one or other of the luminous spots, and occasionally both, and had made upwards of one hundred and twenty drawings. Since April 5 in the present year he had not lost sight of the northern spot, which alone was visible at that date. He did not find the spots affected by the diurnal rotation of the planet, and hence infers that the axis passes either through or very close to their centre. In this view it will be interesting to compare the position of the axis of the spots determined by his observations with the results obtained by De Vico and others. An attempt in this direction, founded upon some of the more satisfactory drawings, did not promise a near agreement. M. Trouvelot adds that the spots appear almost permanent, and thinks they are the summits of high mountains projecting beyond the cloudy envelope, generally opaque, which covers the planet.

The observations in 1877-78 were made at Cambridge, U.S., those of the present year at the Observatory of Meudon. De Vico's investigation on the position of the axis of Venus appeared in the *Memoirs* of the Observatory of the Collegio Romano for 1840-1841: it can hardly be said that his results, founded upon data necessarily vague, have inspired much confidence amongst astronomers. He made the inclination of the equator of Venus to the ecliptic 53° 11′, and the longitude of the ascending node 57° 19′ for 1841; the rotation of Venus in sidereal time, 23h. 21m. 21·93s.: these are the figures quoted in Secchi's "Life of De Vico."

THE GREAT COMET OF 1882.—Prof. Howe notifies that he has undertaken a definite determination of the orbit of this comet, which will doubtless be a work of some labour. Thus far calculation appears to indicate that the comet was moving in an ellipse, with a period not differing much from eight centuries: Kreutz gave 843, Fabritius 823, Frisby 794, and Morrison 712 years; the orbit of Fabritius depends upon the widest extent of observation. Between the earliest and latest accurate positions the comet described an orbital arc of 340°: a similar arc was traversed by the comet of 1680 between its discovery by Kirch on the morning of November 14 and the last observation by Sir Isaac Newton on March 19 following.

Those who may have unpublished observations of position of the great comet of 1882 will do well to communicate them to Prof. Howe forthwith.

BRORSEN'S COMET OF SHORT PERIOD.—We have not yet met with any intimation that an ephemeris of this comet for the approaching reappearance is being prepared: that for the last return in 1879 was furnished by Prof. L. R. Schulze of Dobeln; the time of perihelion passage was about eleven hours later than his calculation gave it. Disregarding perturbation, the comet would be again due at perihelion in the middle of September next, in which case it would be observable in the two hours before sunrise, in August and September, under somewhat similar conditions to those in 1873. Supposing the perihelion passage to occur September 14·5, the comet's position at that time would be in about R.A. 154°·5 and N.P.D. 76°·2, the distance from the earth 1·41.

Since the discovery of this comet within one day of perihelion passage in 1846 it has been observed at four returns, viz. in 1857, 1868, 1873, and 1879.

THE IRON AND STEEL INSTITUTE

THE annual meeting of the Iron and Steel Institute took place at the Institution of Civil Engineers on April 30 and May 1 and 2. The proceedings commenced with the reading of the Council's Report and the Accountant's statement, and with the presentation of the Bessemer Medal jointly to Mr. E. B. Martin of Dowlais and Mr. E. Windsor Richards of Middlesbrough, in recognition of the part taken by them in introducing the basic process for the manufacture of steel. In returning thanks, Mr. E. Windsor Richards mentioned that his firm, that of Messrs. Bolckow, Vaughan, and Co., were now making no less than 3000 tons per week by this process from Cleveland pig-iron, such as would have been thought, until recently, wholly unsuitable for steel-making. Sir H. Bessemer, who was present, congratulated the recipients and the steel trade generally upon the brilliant success of Messrs. Thomas and Gilchrist's invention.

The first paper read was by Mr. I. L. Bell, F.R.S., and dealt with the use of Raw Coal in the Blast Furnace. It pointed out that this question, as being more complicated than that of coke, had never been treated before the Institute, although raw coal was largely used in the United States in the form of anthracite, and in Scotland in the form of the splint coal of the Lanarkshire coal-field. It is with the latter that the paper was chiefly concerned. Taking the Brockwell seam as a good specimen of Durham coking coal, analyses were given of it first in its raw state, and secondly when converted into coke, together with the number of heat units developed from one weight-unit of each. It appears that this number is 7437 in the case of the coal, and 7395 in the case of the coke, so that the heat developed in the two kinds of fuel is practically the same. This theoretical result was checked by experiments on a large scale made upon the North-Eastern Railway, using the same engines and the same weight of trains. The trials were continued for one week with each kind of fuel, full loads being taken to the place of shipment and the waggons returned empty to the collieries. The result in one trial in pounds consumed per train mile was 40·5 of coal and 41·6 of coke. In another experiment the difference was larger, but still it was not serious, and the theoretical deduction just given is thus fully confirmed. This equality of value between coal and coke is not, however, found to exist in the blast furnace, for the simple reason that the volatile constituents of the coal are scarcely oxidised at all, and therefore give but very little useful effect. They might, however, be utilised in another way, namely, as a means of reducing the oxide of iron to the metallic state. The gas from the coal would thus do part of the work now done by CO, and might enable a larger quantity of CO_2 to be evolved in the escaping gases. At present, however, this effect does not seem to be realised in practice. Analyses were given of the Lanarkshire splint coal, which show that, as a source of heat, it is inferior by about 30 per cent. to the South Durham coal. Analyses were also given of the escaping gases where this coal is used for smelting, and from this the quantity of heat evolved and appropriated was calculated, and compared with furnaces using coke. It thus appears that the raw coal occasions a much less perfect oxidation of the carbon, and in consequence a much smaller evolution of heat. On the other hand, the hydrogen contained in the coal affords a large supply of heat, but this and far more is absorbed in the expulsion of the volatile constituents, which is sufficiently proved by the very low temperature of the escaping gases, 190° C. as compared with 332° C. in the case of coke.

As regards the proportion of CO_2 and CO in the escaping gases, it appears that with coal it is much below the limit which Mr. Bell has fixed as the maximum compatible with reduction, viz. 1 of CO_2 to 2 of CO. Hence it follows that a considerable quantity of CO_2 must have dissolved carbon and so returned to CO. Calculating this quantity, it appears that the total carbon which reaches the hearth and gives up its heat for the fusion of iron, &c., is not very different in the two cases. Why then is there so large a disappearance of CO_2 in the Scotch furnace as compared with the English? Mr. Bell attributes it to the fact that the latter is 80 feet high, whilst the former, though 74 feet high, was only filled to 85 per cent. of its real capacity. The effect of the lower furnace is to diminish the time during which the ore is exposed to the reducing agency of CO, whilst still too cool for the fuel to decompose CO_2. In addition it is suggested that the presence of hydrogen in the coal might cause the formation of steam, which would subsequently react on the fuel and tend to lower the percentage of CO_2. On the whole it appears that when using raw coal in the blast furnace there is a waste of carbon to the extent of 3·72 units; but before recommending that the coal should be coked in order to avoid this loss, the commercial aspect of the question must be considered, and it appears that the cost of coking even where possible would in many cases exceed the saving attained. A further point, however, which needs consideration is the possibility of condensing the tar and ammonia given off by the coal and so saving the valuable products. Here we have a difficulty in the Scotch furnaces from the enormous quantity of gas which would have to be dealt with; nevertheless the results attained by Messrs. Baird in the Gartsherrie furnaces (given below) seem to show that the yield of ammonia is about the same as in the Simon-Carvès process for coking, as used

by Messrs. Pease, in which case the sulphate of ammonia and tar were worth about 3*s.* per ton of coal used. As theoretically five times this amount of sulphate of ammonia might be obtained from the coal, it seems probable that a large quantity of nitrogenous compounds may eventually be secured in this manner.

In the discussion on the paper, the fact of coal and coke being practically equal in heating power was confirmed by several speakers; and some interesting facts as to the anthracite blast furnaces of the United States were elicited. The advantages of calcining the limestone (which seem in most cases to be *nil*) and of mixing coke with coal in the charge were also discussed; and the important question of raw coal as an iron-smelting material may thus be said to be fairly opened.

The next two papers were taken together. The first was by Mr. R. Smith Casson on the system worked out by himself and M. Bicheroux for gas puddling and heating furnaces. This system, which has been worked with most satisfactory results in Belgium, is simpler and cheaper than that introduced by Sir William Siemens, and as regards efficiency and economy has much to recommend it. The other paper, by Mr. W. S. Sutherland, was on the most recent results in the application and utilisation of Gaseous and Liquid Fuels. It appears that Messrs. Baird and Co. are now recovering the tar and ammonia from the gases of no less than sixteen of their blast furnaces, consuming about 100 tons of coal daily. They manufacture the ammonia into sulphate and distil the tar, the actual yield per ton of coal varying from 18 lbs. to 25 lbs. of sulphate of ammonia, and from 180 lbs. to 200 lbs. of tar. The gas is found to be perfectly clean and free from moisture, and is thus better adapted than before to such purposes as raising steam, heating the blast, &c. In addition to this the paper described a new method of working the producers employed for generating gas in the Siemens or other systems of gaseous fuel, and for abstracting from the gas so obtained the tar and ammonia it comprises. It appears that a generator gas of high quality can now be got with certainty, at the same time yielding 20 lbs. of sulphate of ammonia with ten to twenty gallons of good tar per ton of coal. A net saving of from 2*s.* 6*d.* to 4*s.* per ton may thus be effected, and with the same result as in the case of the blast furnace, viz. that the gases are improved instead of being damaged by the removal of their valuable products. The using of such substances as tar and ammonia merely for fuel can only be considered barbarous, and it now seems probable that in a very few years it may be a thing of the past.

On Thursday the first paper read was by Mr. Walter R. Browne on Iron and Steel Permanent Way. It described the system of iron sleepers, successfully introduced by Mr. Webb of the London and North-Western Railway, and pointed out the many advantages that would result, especially to the iron trade of this country, if the use of metallic sleepers became a recognised fact. In Germany it is so already, thousands of miles being now laid with metallic sleepers; and it is to be hoped that a vigorous effort will be made to develop their use both in England and in our colonies.

The second paper, by Capt. C. Orde-Browne, R.A., dealt with the behaviour of Armour of different kinds under fire. Four kinds of armour were specified: first, wrought iron; secondly, compound armour or wrought iron with a steel face; thirdly, solid steel; fourthly, chilled cast iron. The different modes in which these yield to the impact of a shot were clearly described. Wrought iron is punched with a clean hole, the rest of the target hardly suffering any damage. As complete penetration is necessary, hardness and rigidity of metal are the essentials for a projectile, and not tenacity. Hence the extended use of Palliser's chilled shot. In compound armour the hard steel face severely tries the tenacity of the metal, so that the shot frequently breaks to pieces; at the same time the plate yields by cracking in radiating lines from the point of impact, and sometimes in concentric lines. Solid steel does not yield at the point of impact, but as the shot enters, it wedges and sets up the metal round it, the plate swelling and yielding by radiating cracks. Such cracks are much more likely to extend through the metal than is the case with compound plates. Chilled iron is broken up bodily by the direct blows of heavy shots, cracks radiating from the point of impact, which is never pierced even to a single inch of depth. Details were then given of the experiments carried out in 1882 at Essen, at Spezia, and at Ochta near St. Petersburg; in 1883, at Shoeburyness, and at Buckau on chilled cast iron; and finally experiments by Capt. Palliser and Sir Joseph Whitworth. Stress was laid on the necessity for dividing armour into two distinct classes, soft and hard: the former signified armour which was perforated, and the latter armour which must be broken up. The difference was illustrated by a simple dropping apparatus, in which a model of a shot with a heavy weight behind it was allowed to fall either upon millboard, to represent soft iron, or upon brick, to represent hard iron. The likeness of the results to those found in practice with hard and soft armour respectively is very remarkable. It is therefore altogether a mistake, when attacking hard armour, to use the data obtained for perforation as a measure of the shot to be employed. The energy in the shot per ton of the weight of the shield is another measure which may be useful, but is not theoretically correct. To work out the problem mathematically is very difficult, and it is suggested that much might be learnt by firing steel bullets against plates of steel and chilled iron, keeping all conditions uniform except those whose relation is the object of investigation. Certainly some such experiments are needed, as are also actual trials against the hard armour, solid steel, or chilled iron, which is much used abroad; otherwise, should we be involved in a war, we might find that our calculations, based only on soft armour, would land us in disastrous failure.

The first paper on Friday was on Recent Improvements in Iron and Steel Shipbuilding, by Mr. William John of Barrow-in-Furness. This paper gave some remarkable statistics of steel-built vessels during the last few years. It appears that between 1879 and 1883 the proportion of steel vessels built and registered in the United Kingdom increased from 4·38 per cent. in 1879 to 15·7 per cent. in 1883; wooden vessels being left out of account in each case. It is evident that steel as a material for shipbuilding has passed entirely out of the experimental stage, and must be judged by the results of its working in the shipyards, and the performance of the ships already afloat. The experience of those shipbuilders who have paid most attention to steel is that it has now become a much more uniform and satisfactory material than iron, so that workmen actually complain if they are put to work upon iron, from the trouble and annoyance it involves. The only point of practical importance left is the deterioration which occasionally occurs when thick plates of steel are punched. On this further information is necessary, as also on the real cause of the failures that took place some years ago, especially those in the boilers of the *Livadia.* In some cases, metal of which the chemical analysis showed nothing abnormal, and which would bend double when the edges were carefully prepared, broke off like glass when the edges were rough, or when holes were punched in it. The paper then went on to consider the difference in cost between vessels built of iron and steel, which at the present rate appears to be practically insignificant. On the other hand, strength is decidedly in favour of steel ships, even with the present reduction of scantlings sanctioned by Lloyd's. The case was mentioned of the *Duke of Westminster,* a vessel 400 feet long, which bumped for a week at the back of the Isle of Wight on stony ground without making a drop of water. This was owing to the elasticity of the steel, and could not possibly occur with an iron ship. With regard to corrosion, Mr. Johns considered that this was a matter to be overcome by increased knowledge and care in maintenance, while there was no evidence to show that the difference in corrosion between steel and iron is sufficient to stop the progress of steel shipbuilding. Finally he observed that great attention had been paid of late to the longitudinal strains on very large ships, much greater use being made of iron decks, longitudinal stringers in the bottom, &c., so that he could no longer show, as he had in 1874, that vessels grew steadily weaker as they increased in size. In the discussion, Mr. Martell, Inspector of Lloyd's, confirmed the view that steel is infinitely superior to ordinary iron, and that there is no reason to suppose that it deteriorates faster. He mentioned a ship built in 1878 for the iron ore trade, which as yet showed no sign of deterioration. On the other hand, Mr. Jeremiah Head mentioned that, despite the progress of steel, more iron had been used in shipbuilding during the last year than ever before, and that steel plates were still much more expensive than steel rails from the necessity of hammering them after rolling. He maintained that common iron did not corrode so much as best iron or steel: the *Great Britain*, built in 1845, is still in existence, and so is a collier built in 1831. Mr. Riley confirmed the necessity of hammering, owing to the increased number of failures if this was neglected. Sir Henry Bessemer and others also took part in the discussion. This concluded the business of the meeting, the remaining papers being adjourned.

THE BUILDING OF THE ALPS[1]

WHEN were the Alps upraised, and what is the age of their building stones? On the former of these questions there is less diversity of opinion than on the latter; yet, notwithstanding all that has been written on both, I am not without hope that I may find a few things sufficiently novel to be of interest to a general audience.

The subject, indeed, is so vast that I must crave your indulgence for leaving some gaps in my reasoning unfilled, and presenting you with little more than an outline. To save time I shall assume a knowledge of the simpler geological terms, asking you only to remember that I always use the word "schist," as I maintain it ought to be used, to denote a more or less fissile rock the constituents of which have undergone so much mineral change that, as a rule, their original nature is almost wholly a matter of conjecture. I must also ask you to remember that, though I have seldom mentioned the names of other workers, I am really doing little more than giving an epitome of the labours of a host of geologists, conspicuous among whom are Heim, Baltzer, Von Hauer, Gastaldi, Lory, Favre, Renevier, and many more, both Continental and English; I select, however, those facts with which I have myself become familiar during many visits to different districts of the Alps, from the Viso on the south to the Dachstein on the east.

It is needless, I assume, to explain that mountain chains are the result of lateral thrust rather than of vertical upheaval, and their contours are mainly due to the sculpturing action of heat and frost, rain and rivers, acting upon rocks bent into various positions, and of various degrees of destructibility. There are, however, three principles which are less familiar, but which I must ask you to bear in mind throughout this lecture: (1) that when a true schist is asserted to be the metamorphosed representative of a post-Archæan rock, the *onus probandi* lies with him who makes the assertion; (2) that rocks composed of the detritus of older rocks may often readily be mistaken for them; (3) that great caution is needed in applying the principles of lowland stratigraphy to a mountain region. The first of these is, I know, disputed, but there can be little doubt as to its accuracy; the second is indisputable, so is the third; but I will briefly illustrate what I mean by the statement. [Attention was then directed to diagrams of folds and reversals of strata in the Alps.]

The first section to which I invite your attention is in the neighbourhood of the Lake of Lucerne. There are few travellers to whom the cliffs of the Rigi are not familiar. Those great walls of rock, along and beneath which the Rigibahn now takes its audacious way, are mainly composed of enormous masses of conglomerate, an indurated gravel of Miocene age, called the nagelflue. These pebble beds may be traced in greater or less development along the north-western margin of the Swiss Alps; they attain in the Rigi and the fatal crags of the adjoining Rossberg a thickness of not less than 2000 feet. The structure and nature of this nagelflue show that it has been deposited by rivers, possibly at their entry into lakes, but more probably, as suggested by my friend Mr. Blanford, on beginning a lowland course at the very gates of the mountains. In this great mass there are indeed pebbles of doubtful derivation; but we need not hesitate to refer the bulk of them to the mountains which lie towards the east, and we may regard the great pebble beds of the Rigi and the Rossberg as built of the ruins of Miocene Alps by the streams of a Miocene Reuss. Now when we scrutinise the pebbles of this nagelflue we are at once struck by a remarkable fact. The Reuss, at the present day, only passes through Mesozoic rocks when it approaches the neighbourhood of the Lake of Lucerne. It is within the mark to say that quite three-fourths of its drainage area consists of crystalline rocks. Hence schists and gneisses abound among its pebbles, and the same rocks are no less frequent among the erratics which have been deposited by the vanished glaciers of the Great Ice Age on the flanks of the Rigi to a height of 2000 feet above the Lake of Lucerne. Yet, on examining the nagelflue, we find that, while pebbles of grit, and limestone, and chert—specimens of the Alpine Mesozoic rocks—abound, pebbles of schist and gneiss are extremely rare. I had searched for hours before I found a single one. The matrix also of the nagelflue—the mortar which makes this natural concrete—when examined beneath the microscope, tells the same story. We do not see in it the frequent quartz grains, the occasional pieces of felspar, the mica flakes, which are records of the detrition of gneissic rocks, but it consists of fragments similar to those which form the larger pebbles. It is therefore a legitimate inference that, in this part of the Alps at least, the protective covering of Mesozoic rock in the Miocene age had not generally been stripped away from the crystalline schists of the Upper Reuss, and that since then the mountains may have been diminished and the valleys deepened by at least a mile vertically. I have spoken only of the valley of the Reuss, but a little consideration will show that my remarks may be extended to a much larger area of the Oberland Alps.

I pass now to two other sections: of these the first is in the neighbourhood of Pontresina. Most of the peaks in this region consist of igneous rocks, of gneisses, and of schists, but some of later date are not wanting—as, for example, may be seen in the flanks of the well-known Heuthal. These last are limestones of Triassic age. Here they overlie unconformably a coarse gneiss—in other places they rest on schists presumably of later date; in fact, the series of Mesozoic rocks of which the above limestone is the lowest member—though now to a great extent removed by denudation—has clearly once passed transgressively over the whole series of gneisses and schists of the Engadine.

The second section, or rather group of sections, is some distance away to the south-east, in the region of the Italian Tyrol. Those magnificent crags of the Dolomite mountains, the serrate teeth of the Rosengarten and the Langkofel, the towers of the Cristallo and the Drei Zinnen, the precipitous masses of the Blattkogel and the Marmolata, are built up of rocks of Triassic age, not of a very different date from the soft red marls which occupy so large an area in the Midlands of England. Follow me for one moment by the mountain road from Predazzo to Primiero. At the former place—classic ground for geologists—we are surrounded by great masses of igneous rocks, the roots, it may be, of long-vanished cones, although we refuse to recognise a crater in the valley about Predazzo. As we ascend towards the beautiful Alps of Paneveggio, we pass for a considerable distance over a great mass of red felstone. This belongs to a group of igneous rocks which extend to the westward even beyond the Etsch. It is overlain by the beds of the Trias, commencing with the red Grodner sandstone and passing up soon into the vast masses of dolomite which form the wild crags of the Cimon della Pala and its attendant summits. But as we descend on the other side of the pass towards Primiero, we see the Triassic rocks, without the intervention of the felstone, resting upon mica schists, similar to those which occur in many other parts of the Alps. Sections of the above kind, were it needful, might be multiplied indefinitely to prove that between the base of the Trias and the Alpine schists and gneisses there is an enormous break, but we may content ourselves with one other, interesting not only for the completeness of the demonstration, but also for the mode in which it illustrates Alpine structure. [Attention was then directed to the section of the Mont Blanc range as given by Prof. Favre.]

The Aiguilles Rouges are composed of coarse gneisses and crystalline schists, but on the highest summit there remains a fragmental outlier of stratified and unaltered rock. The upper part of this is certainly Jurassic. Below this comes a representative of the Trias—much attenuated, as it is generally in this western region, with possibly a remnant of a deposit of Carboniferous age. Be that as it may, there is undoubtedly here a great break between the crystalline series and the succeeding Mesozoic or Palæozoic rock.

There remains yet one other section to which I wish to direct your attention; it is near Vernayaz, in the vicinity of the famous gorge of the Trient. Where the Rhone bends, at Martigny, from a south-west to a north-west course, the crystalline *massif* of the Mont Blanc region of which we have just spoken crosses the river, and is lost to sight as it plunges beneath the Mesozoic rocks of the western summits of the Oberland. The gorge of the Trient is cut through hard and moderately coarse gneiss; the same rock occurs at the Sallenche waterfall. Between the two is a mass of rock of a totally different character—in part a dark slate, like some in Britain of Lower Silurian age; in part a conglomerate or breccia in a micaceous matrix, proved by its plant remains to be a member of the Carboniferous series. Omitting some minor details, not without interest, it may suffice to say that we have in this place the end of an almost vertical loop, formed by the folding of beds of Carboniferous age between the crystalline rocks, which are the foundation-stones of the district. The conglomerate is at the base of the Carboniferous

[1] Lecture by Prof. T. G. Bonney, D.Sc., F.R.S., Pres. G.S., at the Royal Institution, April 4.

series, and its matrix so closely resembles a mica schist that it has been claimed as indicating metamorphism, and as linking together the Carboniferous slates and the crystalline schists. But, in the first place, the fragments in the conglomerate are not only gneisses and schists, but also ordinary slaty rocks, no more altered than those of Llanberis. How, we may well ask, could the latter escape unchanged when all the surrounding matrix was converted into mica schist? Further, when we apply the test of the microscope—that Ithuriel spear by which the deceits of rocks are so often revealed—we find that this seeming mica schist is only the consolidated debris of micaceous rocks. Its composition, and that of the conglomerate, justifies us in asserting that when the Carboniferous rocks of the Valorsine were deposited there were land surfaces of gneiss and schist in the western region of the Alps, and that these rocks were substantially identical with those through which the Trient has sawn its ravine.

It would be easy to multiply instances similar to one or the other of those quoted above for this or that district of the Alpine region, from the south of Monte Viso to the north of the Adriatic, to speak only of those districts of which I have a personal knowledge; but I should speedily weary you, and will ask you to regard these as typical cases, single samples of a great collection. They justify, as I think you will agree, the following inferences:—(1) That there has been one epoch, at least, of mountain-making posterior to the deposition of the Miocene nagelflue, which has given to many parts of the Alpine chain an uplift sometimes not less than a mile in vertical elevation; (2) that prior to this there was an earlier epoch of mountain-making, which affected all the rocks of older date, including at any rate a portion of middle Eocene age—for we find marine strata of this date crowning the summit of the Diablerets, now more than 10,000 feet above the sea, and bent back, as at the Rigi Scheideck, over the beds of the nagelflue; (3) that there was a pre-Triassic land surface of great extent, largely composed of crystalline rocks, and that with this geological age commenced a long continuous period of depression, lasting into Tertiary times; (4) that a land surface of considerable extent existed at a yet earlier period, and that this in the Carboniferous age was watered by streams and clothed with vegetation—whether there were mountains then it is impossible to say, but the evidence certainly points to the conclusion that the ground was hilly; (5) that anterior to the last-named period there is a great gap in our records; the older rocks, whose stratigraphical position can be ascertained, being much metamorphosed, so that we appear justified in concluding that all the more important mineral changes which they had undergone occurred in pre-Carboniferous times—that is, that the later Palæozoic land surfaces consisted of gneiss and schists in all important respects identical with those which now exist.

I have thus led you step by step—by processes, I trust, of cautious induction—to the result that the Alps, as an irregular land surface, are a very ancient feature in the contour of the earth, and that the gneisses and crystalline schists, whereof they so largely consist, are rocks of very great antiquity. Let us now attempt to advance a step further by attacking the problem from another side. Hitherto we have been working downwards from the newer to the older, from the rocks of known towards those of unknown date. Beginning now in the unknown, beginning with the most remote that we can find, let us proceed onwards toward the more recent and more recognised.

This is a task of no slight difficulty. The ordinary rules of stratigraphical inference frequently fail us; nay, if blindly followed, would lead us to the most erroneous conclusions. In the apparent succession of strata in a mountain range the last may be first and the first last in the literal sense of the words. Beds may be repeated again and again by great folds, now in the direct, now in the inverse, order of their superposition. They may have been faulted and then folded, or folded and then faulted, and the difficulty is augmented by the vast scale on which these earth movements have taken place, by the frequent impossibility of scaling the crags or pinnacles where critical sections are disclosed, and by the masking of large areas of surface by snow and glacier, or by debris and vegetation. Yet more, the consciousness of these difficulties produces in the mind—I speak for myself—a sort of hesitation and scepticism, which are most unfavourable for inductive reasoning. Knowing not what features are of importance, one is perplexed by the variety of facts that seem to call for notice; knowing how easily one may be deceived, one hesitates to draw conclusions. I am often painfully conscious of how much I have lost in a previous journey from not having remarked some fact to which a fortunate accident has just compelled my attention. In this part, therefore, I must be pardoned if I speak with considerable hesitation and do not attempt more than state those inferences which seem to me warranted by facts.

I shall again ask permission to conduct you to a series of typical sections, which, however, I shall describe with less minuteness.

Let us place ourselves in imagination on the great ice-field at the upper part of the Gross Aletsch Glacier—the Place de la Concorde of Nature, as it has been happily termed. We are almost hemmed in by some of the loftiest peaks of the Bernese Oberland: the Aletschhorn, the Jungfrau, the Mönch, and several others. We find the rocks which rise immediately round the glacier—as, for example, near the well-known Concordia hut —to be coarse gneisses, with difficulty distinguishable from granites. As the eye travels up to any one of the mountain ridges, the rock evidently becomes less massive and more distinctly foliated. We note the same sequence as we retrace our steps towards the Rhone valley—speaking in general terms, the ridges and the flanks of the Eggischhorn consist of more finely granulated gneisses and of strong micaceous schists, which alternate more frequently one with another. Further to the west, in the region around the Oberaletsch Glacier and on the slopes of the Bell Alp, we find the same succession—coarse granitoid gneisses in the relatively lower part of the heart of the chain, finer grained and more variable gneisses and schists on the upper ridges and the southern flanks.

Let us change our position to a spot considerably to the east, to the great section of the crystalline series made by the valley of the Reuss below Andermatt.

From the spot where the rocks close in suddenly upon the torrent near the Devil's Bridge, to a considerable distance below Wasen, extends an almost unbroken mass of coarse granitoid gneiss. This, however, becomes more distinctly bedded and schistose before it entirely disappears beneath the Secondary deposits that border the Bay of Uri. Similarly, if from Wasen, where the gneiss is barely distinguishable from granite, we ascend the wild glen which leads up to the Susten Pass, and descend on the other side by the grand scenery of the Stein Alp to the beautiful Gadmenthal, thus passing obliquely outwards along the apparent strike of the rocks to the point where, as in the neighbourhood of the Imhof, they disappear beneath Mesozoic deposits, we again find that we are among rocks which are rather more variable in their mineral character, oscillating between moderately coarse gneisses, sometimes porphyritic, and strong mica schists. Near Muhlestalden, in the Gadmenthal, even a bed of white crystalline dolomitic limestone is interstratified with the gneissic rocks.

Leaving for a brief space the vicinity of the St. Gothard road, and returning to the upper valley of the Rhone, let us place ourselves on such an outlook as we can obtain from Prof. Tyndall's châlet on the Bell Alp, and fix our eyes on the magnificent panorama of the Pennine chain, with whose geology we will suppose ourselves to have become familiar in frequent traverses from the northern to the southern side of the watershed of Central Europe. Facing us, and forming the lower slopes and crags of the great mountain chain of the Pennines, we see an enormous mass of distinctly bedded rock, of a brownish tint, of which at this distance we should hesitate to say whether we ought to regard it as a member of the metamorphic or of the ordinary sedimentary series. In an east-north-east direction we see it gradually rising to form the peak of the Ofenhorn and the upper part of the mountains about the Gries Pass. In the opposite direction it forms the lower slopes of the Simplon Pass and the portals of the valley of the Visp. Hence, could we follow it, the area occupied by this rock broadens out into the spurs which inclose the Einfischthal and the Eringerthal, and crosses the watershed towards the south to the east of the St. Bernard Pass. In more than one locality in the region of the Binnenthal a band, of no great vertical thickness, of a white crystalline dolomite is conspicuously present. A very similar group of rocks occurs in the Val Piora, in some bands of which black garnets are very abundant. The same mineral also occurs in a similar rock near the summit of the Gries Pass. Andalusite or staurolite also occurs occasionally; the group, in short, is well characterised, and for reference I will call it the Lustrous Schists.

I pass now to the neighbourhood of the St. Gothard. The coarse gneiss, which is pierced by the northern entrance of the great tunnel, ends abruptly at the Urnerloch. The basin of the Urserenthal is excavated from satiny slates, with dark limestones, very possibly of Jurassic age, and from some underlying rather variable schists. The first rock visible on the eastern side as we approach Andermatt is a schistose crystalline limestone, associated with mica schists; and a series of rather variable schists, evidently very different from the coarse gneisses of the gorge below, appears to cross the valley, and form the slopes leading to the Oberalp Pass. These may be traced for some distance up the Furka road above Realp, when they are abruptly succeeded by the slaty group mentioned above. I am convinced that they are much more ancient than the latter, being probably members of the Lustrous Schist group, if not older. It is obvious that the newer rocks are only a fragment of a loop of a huge fold, over which on either hand the fragments of the enveloping older metamorphic rocks tower up in mountain peaks. On the ascent of the St. Gothard Pass from Hospenthal a series of somewhat variable micaceous schists continues till the top of the first step in the ascent is reached, about 800 feet above the valley, when gneiss sets in, generally rather coarse and sometimes very porphyritic, occasionally interbanded with dark, rather friable mica schists. The upper plateau of the pass consists of a porphyritic rock, often called granite, but with a gneissose aspect and rather more friable in character than the rock of the Wasen district. On the first steep descent on the south side this rock appears to pass into a normal coarse gneiss, occasionally banded with mica schist, resembling that in a similar position on the northern flank, which is succeeded for a short space by a remarkably well-banded gneiss. To this succeeds—it must be remembered that the series is inverted in order—the great group of hornblendic and garnetiferous mica schists, which continue along the Val Tremola and the lower slopes of the mountain to the neighbourhood of Airolo, where some calcareous rock occurs, being probably an infold of much later date.

Through the kindness of Mr. Fletcher and Mr. Davis, of the British Museum, I have been allowed to examine the series of specimens from the St. Gothard Tunnel in that collection. They correspond in general with the succession above indicated, except that I have failed to identify the granitoid rock of the summit plateau. Leaving, however, for a moment the question of correlation, we see that the St. Gothard section presents us with an instance of folding on a gigantic scale, and of the fan structure, doubtless with many minor flexures and faults.

In the neighbourhood of the Val Piora we get an important succession. The ascent to the hotel from the Val Bedretto passes in the main over a series of micaceous schists and rather friable gneisses, which are a prolongation of an axis exposed in the mountains south of Airolo and fairly correspond with much of the rock (excepting the granitoid) forming the upper part of the St. Gothard Pass. To this succeeds a series which, though more calcareous, clearly represents the garnetiferous actinolitic series of the southern slopes, and to this a group closely resembling the Lustrous Schists.

(To be continued.)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The Electors to the Professorship of Pathology will meet for the purpose of electing a Professor on May 24. The stipend of the Professor is 800*l*. a year, exclusive of fees, but he must not engage in the private practice of Medicine or Surgery.

Prof. Macalister lectures to-day on the Race Types of the Human Skull; on Saturday, on the Race Variations of the Skin, Hair, and Soft Parts; and on Tuesday, the 13th, on the Anatomical Characters of the Prehistoric and Early Historic Races of Britain: on each day at 1 p.m.

In the Long Vacation Prof. Macalister will take a Class in Osteology, and the Demonstrator will have a class for Practical Histology.

The new buildings for Prof. Stuart's Museum of Mechanism will be ready to receive their contents this term, and it is recommended that the buildings to provide for the Department of Botany be at once proceeded with, to be ready for use at the beginning of October.

LONDON

Royal Society, May 1.—"On the Connection of the Himalaya Snowfall with Dry Winds and Seasons of Drought in India." By Henry F. Blanford, F.R.S.

In this paper the author points out that for some years past it has been suspected that the snowfall of the Himalaya has a direct influence on the dry land winds of North-Western India. The connection of the two was first noticed in 1876 and 1877, the first-named a year of drought and famine in Southern India, the second the same in the North-Western Provinces, Rajputana, and Central India. Messrs. Hill and Archibald, about the same time, called attention to the circumstance that excessive winter rainfall in Northern India is usually followed by defective rains in the summer or monsoon season. This inference is strengthened if the rainfall of May be included in that of the winter and spring instead of in that of the summer, as is shown by a table for the eighteen years from 1864 to 1881 inclusive. Fourteen of these years give results agreeing with Messrs. Hill and Archibald's views, and only four differ from their conclusions: two out of these four, viz. 1876 and 1880, being found on further investigation distinctly to confirm the theory, whilst data are wanting with regard to the other two years.

After some details concerning the meteorology of the area in the years 1881–82, the writer gives a description of the unusual snowfall on the outer ranges of the Himalaya in the spring of 1883, and of the extensive drought in Northern, North-Western, and part of Central India that followed. In this instance a warning forecast of dry weather and retarded rainfall was published in the *Gazette of India* on June 2, and this forecast is shown to have been justified by the event, the rainfall in July and August over large portions of India having been much below the average.

In an account of the meteorology of the land winds it is shown that from November to February they tend to circulate anti-cyclonically round the axis of maximum pressure, extending from the Punjab and Sind across Rajputana and Central India towards Orissa. In March a barometric minimum is established over the Hyderabad plateau, and this extends to the north and north-east, the wind currents becoming cyclonic around the depression. To the eastward of this area some rain falls in the spring, but Western India from Belgaum to the Punjab is practically rainless from November till May, and is the dry wind area. It is then shown that the supply of air for the dry wind is derived from an upper stratum by convective interchange. After rain and snow on the Himalayas the dry winds are supplemented by an outflow of cold air from the hills accompanied by a wave of high pressure advancing eastward from the valley of the Indus.

The following summary and conclusions are given:—

(1.) The experience of recent years affords many instances of an unusually heavy and especially a late fall of snow on the North-Western Himalaya being followed by a prolonged period of drought on the plains of North-Western and Western India.

(2.) On tabulating the average rainfall of the winter and spring months at the stations of the North-Western Himalaya, year by year, for the last eighteen years, and comparing it with the average rainfall of the North-Western Provinces in the ensuing summer monsoon, it is found that with four exceptions an excessive winter precipitation on the hills is followed by a deficient summer rainfall on the plains, and *vice versâ*. Of the four apparent exceptions, two are found to afford a striking support to the first proposition.

(3.) The west winds which, in Western and Northern India, are characteristic of seasons of drought as abnormal winds, are identical in character with the normal winds of the dry season, and appear to be fed by descending currents from the North-Western Himalaya, and possibly the western mountains generally.

(4.) It is a common and well-known phenomenon of the winter months that a fall of rain and snow on the North-Western Himalaya is immediately followed by a wave of high pressure advancing eastwards from the western mountains, accompanied with dry cool north-west winds.

(5.) The conclusion is that an unusual expanse of snow on the North-Western Himalaya, whether due to the unmelted residue of an unusually copious winter snowfall, or to an unusually late fall in the spring months, acts, at high levels, in the summer months, in somewhat the same way as the ordinary falls of snow and rain on the Lower Himalaya do at low levels in the winter

season, and favour the production of dry north-west winds on the plains of Western India.

(6.) That this dependence of dry winds on the Himalayan snowfall affords a criterion for forecasting the probabilities of drought in North-Western and Western India.

In setting forth the above conclusions, it is, however, necessary not to ignore the fact that there are other conditions besides those here considered which exercise a very great influence on the prevalence of dry winds and drought. During the last famine period in India (the years 1876 and 1877; in the former year in Southern India, in the latter in the North-Western Provinces and Rajputana), the pressure of the atmosphere was persistently and abnormally high, and this was due, as I showed in the reports on the meteorology of those years, to the condition, probably the high density, of the higher atmospheric strata. Moreover, this excessive pressure was shown to affect so extensive a region that it would be unreasonable to attribute it to the condition of any tract so limited as a portion of the Himalayan chain; and if dependent on the thermal conditions of the surface, which may indeed have been the case, this land must rather have been the major portion of the Asiatic continent than merely a relatively small portion of its mountain axis. This question must remain for future inquiry. It is referred to here to guard against too wide an application being assigned to the action of the Himalayan snows.

Physical Society, April 26.—Dr. Guthrie, president, in the chair.—New Members: Mr. Chattock, Mr. Inwards.—Profs. Perry and Ayrton read a paper on the indicator diagram of a gas-engine, which was intended to teach practical engineers a new method of studying gas-engine diagrams. The most recent results obtained by the use of Dowson gas were stated, and it was suggested that before long gas-engines will be employed for the propulsion of ships. A large wooden model of an Otto gas-engine enabled the operations going on during a cycle of the engine to be understood. Tables were given of the constituents of coal-gas and Dowson gas, the air required for combustion, the heat of combustion, and the specific heats, to enable the characteristic equation of the fluid used in the gas-engine to be determined. An easy method of obtaining one empirical formula to represent all the diagrams which can be obtained from an engine with different quantities of gas was described and its results compared with observation. The effects of vibration of the indicator spring in the various parts of the diagram were discussed, as well as the effect of the last explosion, which are provided for in the empirical formula. Three practical methods of determining the rate, q, of gain of heat by the fluid during the forward stroke were given, and a diagram was shown in which this rate could everywhere be compared with the rate of doing work. If W is the indicated work in one cycle, it was shown that 5·64 W is the total energy of combustion of one charge, and this is expended as follows:—1·45 W is the work done in the forward stroke, 2·22 W is given to the cylinder by radiation in the forward stroke, 1·5 W is carried off through the exhaust-pipe, 0·47 W is given to the cylinder as heat after exhaust-valve opens. The rate at which the loss, 2·22 W., by radiation occurs at every point of the forward stroke was shown on a diagram obtained from a knowledge of the temperature at every point in the stroke, and when the ordinates of this diagram were added to the q diagram previously described, a diagram was obtained showing at every point of the stroke the rate at which combustion was going on. This diagram was specially important as showing the effect of dissociation in the gas-engine.—Dr. W. H. Stone exhibited a simple form of siphon mercurial barometer with metrical scale. Two millimetre scales are adjusted to slide easily side by side; the lower edge of one is brought on a level with the mercury in the shorter limb, and the other slid up and down until its lower edge coincides with the upper mercury surface. The adjustment is easily effected by an observer without stooping by the use of two right-angled glass prisms fitting on the upper and lower ends of a vertical glass tube.—The next meeting of the Society, on May 10, will be held in the Mason College, Birmingham.

Anthropological Institute, April 22.—Prof. Flower, F.R.S., president, in the chair.—The President, in welcoming the Members to their new quarters, gave an outline of the history of the Society and of the eminent men who have presided over it during the forty years of its existence. The Ethnological Society, founded in 1843, and the Anthropological Society twenty years later, were united in 1871 under the title, "The Anthropological Institute of Great Britain and Ireland."—The Marquis of Lorne sent to express his regret at his inability to attend; he exhibited a large collection of North American objects, including a scalp taken last summer.—Sir Richard Owen communicated a paper on a portrait of an aboriginal Tasmanian. The paper was further illustrated by two busts and several portraits belonging to the Institute.—Prof. Keane then read a paper on the ethnology of the Egyptian Soudan, which was described as a region of extreme complexity, a converging point of all the great races of the African Continent, except the Hottentot and Bushman. Although official documents such as Col. Stewart's "Report on the Soudan" for 1883, recognised only "two main divisions, Arab and Negro," it was shown that here was represented the Hamites, Semites, Nubians, Negroes, and Bantus. Of the Hamites, the chief branches were the Tibbu in Darfur, and the Ethiopians stretching east of the Nile without interruption from Egypt to the Equator, and including the Galla and Somali south of Abyssinia, various tribes between Abyssinia and the coast, and the Bejas, who occupied the greater part of the Nubian Desert between Abyssinia and Egypt. The Bejas, whose very existence was ignored by our officials, and who were universally confounded by newspaper correspondents with the Arabs, were the true aboriginal element in the country between Berber and Suakim, where they recently came into collision with the British forces.

Royal Microscopical Society, April 9.—The Rev. W. H. Dallinger, F.R.S., president, in the chair.—On the motion of the President a vote of condolence with the R. Accademia dei Lincei on the death of their president, Quintino Sella (an *ex-officio* Fellow of the Society) was passed.—Dr. Carpenter, C.B., explained in detail his reasons for considering that binocular vision in the microscope took place on the same principles as in the case of ordinary vision, and combated Prof. Abbe's view to the contrary. A number of photographs, diagrams, and models were exhibited in illustration. Mr. Crisp gave his reasons for considering that Prof. Abbe was right. In ordinary vision we had a perspective shortening of parts of the object, but under the microscope this did not occur. In ordinary vision a lined object would show the lines closer together when viewed obliquely, whilst under the microscope the lines appeared the same distance apart whether they were viewed by the central or oblique pencils.—Mr. Bolton exhibited the interesting Rhizopod, *Clathrulina elegans*, from Epping Forest, which had been found to exhibit a fourth mode of reproduction by the formation of flagellate monads.—Mr. Guimaraens described a true *Xanthidium* from Halifax coal strata.—Mr. Badcock read a note on certain filaments which he had observed protruding from *Surirella bifrons*.—Mr. Nelson explained the method which he had found most suitable for examining certain bacteria.—The President announced that the next meeting would be made special, to consider the question of the admission of ladies as members of the Society.

PARIS

Academy of Sciences, April 28.—M. Rolland in the chair.—Observations extracted from M. Verbeek's report on the Krakatoa eruption of August 26, 27, and 28, 1883, by M. Daubrée.—Note on the problem to determine the degree of all algebraic surfaces which may be osculatory with another surface, by M. de Jonquières.—On an extension of the law of Harriot relating to algebraic equations, by Prof. Sylvester.—Memoir on the conservation of stellar energies, and on the variation of terrestrial temperatures, with a table showing the probable succession of the approximate dates of maximum and minimum intensity of solar radiation, by M. Duponchel.—On the absolute standard of light, by M. J. Violle. In this paper the author develops the idea already formulated by him at the International Congress of Electricians in 1881, the essential object of which was to verify the principle of the method, which consists in taking as a standard of light a metal at its point of fusion. He now finds that platinum best fulfils the conditions required of an absolute standard of light. It rests on a perfectly defined and constant physical phenomenon, and constitutes a practical term of comparison with ordinary standards.—Results of a series of experiments undertaken to determine the dimensions of the column of mercury at zero which represents the unity of practical resistance, or the value of the ohm, by MM. E. Mascart, F. de Nerville, and R. Benoit.—Note on the application of the laws of induction to the helio-electric theory of the perturbations of terrestrial magnetism, by M. Quet. From his own observations, as well as those of Carrington, Armstrong, and others, the author infers a definite relation between

the sunspots and terrestrial magnetic disturbances.—On the apparent resistance of the voltaic arc usually employed in lighthouses, by M. F. Lucas.—Some results of repeated experiments conducted at the School of Telegraphy on telluric electric currents, by M. E. E. Blavier.—Description of a method for directly determining the cause of the deficit in dynamo-electric machines, by M. G. Cabanellas.—On the freezing point of the salts of biatomic metals, by M. F. M. Raoult. This paper is accompanied by tables of results for a large number of biatomic metals.—On the formation of amides in separating sal ammoniacs from organic acids, by M. N. Menschutkin.—On a glucoside yielded by the Boldo (*Boldoa fragrans*), by M. P. Chapoteaut.—Researches on water-tight substances; influence of baking and carbonic acid on the induration of siliceous cements, by M. Ed. Landrin.—On the presence of manganese in wines and a large number of other vegetable and animal products, by M. E. J. Maumené. An appreciable proportion of manganese was found in thirty-four wines tested by the author, who infers that it exists in all wines, as well as in wheat, rye, and many other substances.—Note on the assimilating properties of the phosphoric acid contained in rocks and in arable lands, by M. G. Lechartier.—Experimental method of determining the physiological combustibility of various substances, with tabulated results, by M. Schützenberger.—Researches on the respiration of plants in the dark, by MM. G. Bonnier and L. Mangin.—Further remarks on the zeolites associated with the dolerites of the Chaux-de-Bergonne district, Puy-de-Dôme, by M. F. Gonnard.—Special distribution and localisation of the motor roots in the lumbo-sacral plexus, by MM. Forgue and Lannegrace.—Geological section of the shaft sunk to a depth of 502·50 metres at Montrond, Loire, presented by M. Laur. At this depth a sheet of mineral water was reached, accompanied by much carbonic acid, which was ejected to a height of 35 metres above the surface.

BERLIN

Physiological Society, March 28.—Dr. Cohnstein communicated observations he had made on rabbits and dogs regarding the nature of the blood of fœtuses and new-born animals. He first counted the number of blood-corpuscles in a cubic millimetre of blood, and found that throughout the whole course of the fœtal intra-uterine state they increased progressively with the age of the embryo, but yet never attained to the number present in the mother's blood. After birth, however, the relative numbers of the two were reversed. The number of blood-corpuscles in the blood of the young one exceeded that in the blood of the mother. The blood of the new-born animal was accordingly thicker than that both of the fœtus and of the mother. Dr. Cohnstein measured the total blood mass in the unborn and new-born young according to a method he communicated in greater detail; and though the results he obtained were very variable, he never found the same relative differences therein as applied to the quantity of blood-corpuscles. The proportion of hæmoglobin of the embryo blood was precisely calculated, and on the whole showed the same variations as the number of blood-cells; yet the increase of hæmoglobin after birth was not so great as that of the number of blood-corpuscles.—In connection with the foregoing statements of Dr. Cohnstein, Prof. Zuntz brought forward his experiments on the subject of the mechanics of the blood-circulation in unborn animals, after describing at full length the apparatus and methods he had employed in this investigation. The results of his observations, carried out mostly on the umbilical vessels, were as follows:—The blood-pressure in the navel artery amounted on an average to about 40 mm. mercury; in the navel vein it showed considerable variations, limited, however, to between 16 and 30 mm. mercury; values very considerably surpassing the normal pressure in the *vena cava inferior* in the case of the full-grown, but which were very simply explained by the fact that the blood in the placenta suffered only very slight resistance. The rate of movement of the blood was considerably less in the fœtus than in the mother. Especially interesting were the results of the analyses of the blood gases, performed in accordance with methods indicated in the address. It was first shown that the blood of the unborn, when kept for some time in a closed vessel, had its proportion of oxygen very quickly reduced, that is to say, the consumption of oxygen on the part of the fœtal blood was very copious and considerably greater than after birth or in the case of the full-grown. This fact was shown by the very appearance of the blood, the bright red blood taken from the navel artery turning dark very rapidly. The proportion of carbonic acid in the blood in the navel artery was about 4½ per cent. higher than in the navel vein, while in the case of the full-grown the difference between arterial and venous blood amounted on an average, as was well known, to 9 per cent. The proportion of oxygen in the fœtal blood was very changing. In the navel artery it averaged about 4 per cent. less than in the navel vein; but even in this latter case the blood was by no means saturated with oxygen. From the gaseous contents of the blood and its circulation an interesting glance was thus obtained into the respiratory process of the unborn.—Dr. Kossel announced that he had succeeded in demonstrating the presence of peptonous bodies in tissue. If the granule-holding blood-cells of birds were treated with water, there remained a loose, flaky mass which shrunk together on the application of hydrochloric acid; the main constituent of the flaky mass was nuclein, and by the acid another substance was freed, which on analysis proved to be a peptonous substance. The circumstance that this peptonous body, which was soluble in water, was not extracted on the first treatment with water, showed that in the blood-corpuscles it was chemically combined with nuclein. A remarkable property was displayed by this peptonous body when treated with ammonia; it became precipitated as coagulable albumen. Such a transformation of a peptone into coagulable albumen was hitherto known only as an effect of high temperature. That it could be effected in such a simple manner Dr. Kossel regarded as a confirmation of his view that peptone was distinguished from albumen by a higher proportion of water.—Herr Aronsohn spoke of his experiments with a view to electric irritation of the olfactory nerves. The nose having been filled with a very weak warm solution of common salt, one electrode, a platinum wire inside a glass tube, was brought close to the olfactory nerve, and the other was directed to the hand or the neck. A constant current of the strength of ·0001 ampere now excited in each case, according to its direction, either on opening or on closing, a quite decided sensation of smell which could be compared with no known scent, not even with that of phosphor or ozone. Now and again, too, a sense of taste was excited at the same time. The direction of the current had no influence on the quality of the olfactory sensation. The appearance of the irritation on closing or opening the constant current corresponded completely with Pflüger's law of spasms (*Zuckungogesetz*).

DANIELL'S "PHYSICS"

Text-Book of the Principles of Physics. By Alfred Daniell, M.A., Lecturer on Physics in the School of Medicine, Edinburgh. (London: Macmillan and Co., 1884.)

AN important and welcome addition to the existing text-books of elementary physics has appeared. Since the days when Arnott's and Golding-Bird's manuals were in vogue, the number of text-books of physics which have appeared in this country is very small as compared with the vast number of excellent manuals for students which have been produced in Germany and France. Many of these are unique. Verdet's "Cours de Physique" stands alone; nothing like it has ever been produced in England. The text-book of Jamin and Bouty, now much enlarged, is also unique, and of semi-mathematical text-books is by far the best, though limited by the curious restriction that seems to cramp all French science,—ignorance of all scientific work that is done outside France. Jamin's smaller *petit traité*, though admirable, is too concise. Daguin's text-book is overloaded: those of Fernet, and of Boutan and D'Almeida unequal in balance, and too obviously cut to suit the narrow requirements of the *baccalauréat*. The same remark applies less strongly to Ganot's excellent "Physique." Those of Moutier and Violle are yet incomplete. In Germany, Müller-Pouillet's "Lehrbuch," recently overhauled and enlarged by Prof. Pfaundler of Innsprück, is a grand and substantial work for students. If it lacks the elegance of Jamin and Bouty, it makes up in solidity and catholicity of information. Its wealth of pictorial illustration is unapproached. Wüllner's "Lehrbuch" is heavy, and his "Compendium" is not what students want. Mousson's "Lehrbuch," now greatly enlarged, is valuable as a work of reference, but might with benefit be pruned. In addition to these we might name hosts of others by Viktor von Lang, Jochmann, von Waltenhofen, Eisenlohr, Koppe, Emsman, R. Waeber, Hessler-Pisko, Paul Reis, Krebs, Crüger, Sumpf, and others. Against this array what can be shown in Great Britain? The English translation of Ganot by Dr. Atkinson has long held sway; its indefatigable editor has long ago filled up the gaps of the original French work; but it has grown almost encyclopædic, and has never quite freed itself from Ganot's academically conservative way of treating physical problems. The lesser elementary Ganot is also excellent in its way,—as a purely introductory book. Besides the translated Ganot we have also the translated Deschanel; a work which, thanks to Prof. Everett, is vastly superior to the original French work, and has proved of great value as a text-book, by reason of the excellent cuts and the valuable mathematical editorial notes. Dr. Everett's lesser "Physics" is also good as a purely introductory work. In addition to these we may mention, though adapted for popular instruction rather than for students' reading, the two volumes of Guillemin on the "Forces of Nature," edited by Mr. J. Norman Lockyer, which have done good work in their way. So far, not a single really English text-book! But, stop; there is one genuinely British and of very original merit, Prof. Balfour Stewart's "Elementary Lessons in Physics." This comparatively small volume may be cited as the first conscientious attempt to rewrite "Physics" from the modern standpoint, namely, on the basis of the doctrine of energy. In this respect it is infinitely ahead of the more ambitious adaptations from French authors, and will probably long keep its place as a text-book for elementary work. We do not forget Galbraith and Haughton's manuals, excellent—and sketchy—as they are; nor the re-edited Lardner volumes, which, in spite of the abilities of Messrs. Carey Foster and Lœwy, are very decidedly of the *réchauffée* order, and should be allowed an honourable burial. There are also C. Bird's handy "Notes," and a volume by Dr. Aveling, of which, the less said the better. This strange poverty in modern text-books would be indeed remarkable were it not that it is more than compensated by the great abundance of splendid text-books on isolated branches of physics which have issued from the press of Great Britain during the past decade. Individual treatises on mechanics, optics, electricity, sound, and heat have to a considerable extent supplanted more general treatises on physics, with great advantage, in the long run, to the solidity of the reader's information. Nevertheless the text-book of physics has its place and its readers. Men who are reading for mathematics, for medicine, or for the army still require in many cases a something more than superficial acquaintance with physics. It is they who buy the Ganots, the Deschanels, and the Balfour Stewarts, and find them more or less adapted to their needs.

Mr. Daniell's new "Text-book of Physics" is addressed to such students as these, and more particularly to those who read physics as a part of their preparation for a medical degree. But there is abundant matter in it for the engineer and the chemist to consider. The work opens with two chapters on the fundamental notions of mass, time, and space, and on the derived kinematical and kinetical quantities. The third chapter deals with measurements, and the fourth with work and energy. All this is only introductory, and occupies but 50 pages. The remaining 570 pages are therefore based upon the doctrine of energy. The chapter on Kinematics which follows is lengthy but admirable. Harmonic motion, and problems connected with the propagation of waves, are expounded with great care. The teaching here, as throughout, bears the impress of the two great living Scotch physicists whom Mr. Daniell names as his masters. The chapter on Kinetics is none the less welcome because the author frankly gives up the misleading term, "centrifugal force." It strikes us that more might have been said with advantage concerning angular motion and the problems relating to couples. A very useful chapter on Attraction and Potential is then introduced: a most sensible step, since too often the notion of a potential function is postponed until the student comes upon it quite unprepared in electrostatics. It may be noticed that a similar course is adopted in the text-book of Jamin and Bouty. Gravitation and the pendulum conclude the kinetic section of the work, which next deals with the properties of matter. In this chapter, which must be extremely interesting to those

who approach the subject freshly, modern ideas come to the front. The question of viscosity of solids and liquids comes prominently forward. The views of Crookes on the "radiant" condition of highly attenuated gases are discussed, and so is also the connection between the liquid and gaseous states. With respect to the alleged continuity between these states, the author does not seem to have quite made up his mind; for though he quotes with approval the proof given by Ramsay, that the so-called critical point is not necessarily a phenomenon of continuity at all, but simply a certain condition of things in which the liquid and its vapour mix, because they have arrived at equal density and cannot keep separate, he seems also to lean to the other view, apparently relying on an unconfirmed observation by Hannay on the solubility of a solid in a gas. The vortex theory of atoms and the existence of the ether are mentioned in this chapter. There is a capital section on elasticity, and another on liquids, in which the molecular phenomena of liquid cohesion and surface-tension are given due weight, as are also sundry matters concerning the kinetics of liquids, often omitted from such text-books. A short chapter on Gases is introduced, and then follows one on Heat. Just fifty-one pages are given to this entire subject; but in those fifty-one pages an enormous amount of useful matter is comprised. There is not a superfluous line or even word. This extraordinary success—for the thing is most successfully done is largely due to the author's fundamental method of starting from the energy doctrine. The chapter on Heat opens with the first law of thermodynamics, and states it thus: "Heat, being a form of energy, can be measured in ergs." The rest of the subject is developed in a masterly way; though probably the student who has read nothing previously in this branch will find it tough. The paragraph on "the six thermal capacities" is very suggestive, and needs clear thinking to follow it. The author adheres, not quite wisely, we think, to the practice of taking as the definition of the calorie or heat-unit, the kilogramme-water-degree unit instead of the gramme-water-degree unit. This is the only case in which the author does not accept the C.G.S. system. Is there any adequate reason why he should not follow the more modern custom and adopt the *calorie mineure* instead of the *calorie majeure?* The chapter on Sound is also well written; and, for the first time, so far as we are aware, we have the notation of the tonic sol-fa system introduced along with staff notation into the discussions of pitch and temperament.

The chapter which succeeds is enough to take away one's breath. Were this a text-book of the stereotyped academic style, one would know exactly what to expect. After Sound, Light: a chat on the velocity of light; the old familiar gray-headed problems of reflection and refraction; a glance at the rainbow and at telescopes and microscopes; and, to wind up, a couple of pages on the spectrum—with the inevitable chromolithographed chart—and two more on polarisation. But this is not the method of our author. He heads his chapter, "Ether-Waves," and after a little preliminary clearing away he launches into radiation and introduces notions on wave-length, heating effects, colour, and on *exchange* of radiations. Prevost's law and Stokes' law lead direct to the analysis of radiations in the spectrum, and to the evidence afforded in the spectrum of the phenomena of transmission, reflection, and absorption. The propagation of waves through the ether next comes up, involving the questions of plane and circular polarisation, and then, after all this,—shades of the immortal Potter and of the revered Todhunter!—come reflection and refraction of light, mirrors, prisms, and lenses! This is indeed a *bouleversement* of the time-honoured custom of giving all attention to geometrical optics, leaving physical optics to take its chance at the fag end. Yet we are persuaded that the method is essentially right. It is to be regretted, however, that the author does not, with all his improvements, adopt Gauss's treatment of lens problems. Perhaps this is solely for want of space; the sin, if it be one, is one of omission only. Separate sections on interference, double refraction, optical instruments, and rotatory polarisation are given. The instruments are briefly but satisfactorily discussed; the ophthalmoscope and stereoscope receiving due attention. The last and longest chapter in the book is devoted to Electricity and Magnetism. This chapter, though abounding in good points, is to our mind the least successful of the whole; it will not satisfy electricians, though it may, and will, give to medical students a very good and thorough insight into the phenomena and laws of electricity. A very useful bibliography of works on physics for further reading closes the book.

One further point strikes us in reviewing the book as a whole—the excellence of the examples chosen to illustrate the problems and remarks. Particularly to medical students will this feature recommend itself. Levers and moments of forces are illustrated at p. 151 by a long list of articulations in the human skeleton. The references on p. 154 to the action of the biceps and deltoid muscles, on p. 138 to Rosapelly's researches, on p. 143 to anæmic disorders, on pp. 252-55 to the relations of the physical processes of osmose and diffusion to the tissues of the body in relation to juices, foods, alkaloids, and to serpent-poisons, will be recognised as giving a distinctive character to the work.

Such criticisms as it remains for us to pass are directed solely to a few points in which the author will do well to modify the work when it shall attain—as it doubtless will—to a second issue. In the section on the rainbow the secondary and tertiary, &c., bows due to multiple internal reflection are apparently confused with the supernumerary bows due to interference. On p. 35 the "watt" is wrongly defined as a unit of work, and equal to 10^7 ergs, whereas it is not a unit of "work" at all, but a unit of "activity," and is equal to 10^7 ergs *per second.* The matter recurs on p. 575, but is not there much mended. The author uses the letters "E.M.D.P.," meaning thereby "electromotive difference of potential," for that which is more commonly denominated "electromotive force," and abbreviated into "E.M.F." We cannot think the change well advised. What would the author do if he came to discuss the formulæ of a dynamo, in which the induced electromotive force is a very different quantity from the difference of potential between the terminals? Would he write both "E.M.D.P."? Again, on p. 625, the author uses "utility" for the quantity commonly called the "efficiency" of an electric motor. This is in itself not ...ps a bad exchange of terms. But the author goes

on to misapply the very same word and to use it in the sense of "activity," saying in effect that (by Jacobi's law) the "utility" is a maximum when the reaction of the motor reduces the supply-current to one-half. The diagram intended to represent Hall's experiment on p. 628 is quite wrong. The statement on p. 503 that the velocity of light is greater in metals than in air is incorrect: the refractive index is greater, therefore the velocity less. The author has most wisely abandoned the use of that most misleading of terms, vapour-tension, and substitutes therefor simply pressure. This is well; but the reform must go further, and should have gone further at the hands of so worthy a pupil of the Scottish school of physical precision. A reference to the index shows apparently that the author uses the word "*pressure*" correctly and consistently in the sense of force per unit area. If this were so, it would be excellent. Unfortunately the text of the treatise is not always consistent. On p. 152 the author talks of applying a "pressure" to a lever, where he does not mean so many dynes per square centimetre, but where he means simply a "force,"—a push. Of course this confusion of language is pardonable: it runs riot throughout every Cambridge text-book of mechanics from Todhunter to Garnett. We had hoped better things here. Again on p. 154 comes the following question:—"A nutcracker 6 inches long has a nut in it an inch from the hinge: the hand exerts a pressure of 4 lbs.: what is the stress on the hinge?" Answer: "The stress on the hinge is the weight of 24 lbs." In the first place the word "stress" is wholly misapplied; for a stress is not a force, but a force divided by the area on which it is applied: and in the second the word "pressure" is equally misapplied, because what is meant is that the hand applies a "force" equal to the weight of four pounds. In like manner the author's general precision of language would lead to the expectation that he would not misapply that unhappy word "tension." Referring to the index it appears that he uses the word tension in four different senses. He speaks of "surface-tension" of a liquid: which is excusable if the words are connected by an indissoluble hyphen. He speaks of voltaic cells being coupled in "tension," where he means united in series. He speaks (p. 522) of atmospheric pressure in an electrified soap-bubble being resisted by "an electric self-repulsion or *tension* over the surface" (as if self-repulsion were a pulling instead of a pushing force!); and lastly, he speaks of the "tension" of a string (p. 142) when he means the pull, not the stress of so many dynes per square centimetre. He is no worse, however, than the majority of writers on the subject. The average Cambridge text-book teems with similar instances, where problem after problem is set to "find the tension in a rope," without the necessary data as to area of cross-section in the rope being given. There is one book on physics, now happily almost extinct, in which the word tension is used in eight different significations!

Lastly, we must congratulate Mr. Daniell on having embodied the latest results of contemporary research in his work. The ordinary text-book is not seldom ten or fifteen years behind in its data, in some cases more. Here, however, we find, absorbed into the fibre of the book, the most recent matter, such as the researches of Lord Rayleigh on the unit of resistance, of Quincke and of Worthington on capillary phenomena, of Guébhard on electro-chemical figures, of Crookes on radiation and "radiant matter," of O. E. Meyer on viscosity, of A. M. Mayer on the analysis of sounds, of Rosenthal on animal heat, of Vierordt and of Chauveau on blood-pressure, of Wintrich on the use of resonators in auscultation, and of Abney and of Langley on dark radiation. A text-book so furnished forth is doubly welcome. S. P. T.

RECENT CHEMISTRY

Experimental Proofs of Chemical Theory for Beginners. By Prof. Ramsay. (London: Macmillan, 1884.)

The Discovery of the Periodic Law, and on Relations among the Atomic Weights. By John A. R. Newlands. (London: Spon, 1884.)

Chemical Analysis as applied to the Examination of Pharmaceutical Chemicals. By Messrs. Hoffmann and Power. Third Edition. (London: Churchill, 1884.)

Chemical Analysis, for Schools and Science Classes. By A. H. Scott-White. (London: Laurie, 1884.)

Facts Around Us. By C. Lloyd Morgan. (London: Stanford, 1884.)

Science of Food. A Text-book specially adapted for those who are preparing for the Government Examinations in Domestic Economy. By L. M. C. (London: George Bell and Sons, 1884.)

An Outline of Qualitative Analysis for Beginners. By J. T. Stoddard. (Massachusetts, 1883.)

THERE is not the least doubt that in English laboratories theory does not occupy a prominent position. Prof. Ramsay is to be complimented on this very small book, which is certainly a valuable attempt to put chemical theory on a practical basis. It consists of a series of exercises on the measurement of temperature, pressure, and weight in connection with gases, &c., and contains very valuable directions and instructions in the manner of reading thermometers and barometers, and representing changes by curves, and also in the graduation of thermometers and other instruments in common use in the chemical laboratory, a work which should not be relegated entirely to a physical laboratory. The work is divided into twelve chapters, in all of which we have very excellent practical exercises on what is commonly known as chemical theories, that is, the sensity of gases, the law of Gay Lussac and Avogadro, on quantivalence, specific heat, and the equivalents of metals, and a short chapter summarising Newlands' work on the periodic law of the elements. We can strongly commend this little book to all students in chemical laboratories.

Mr. Newland's little book, as the author says in his preface, contains an exact reprint of all the papers on relations among the atomic weights and on the periodic law written by himself and printed in the *Chemical News* during the last twenty years. In its present form it is a desirable addition to our literature, and should bring Mr. Newlands' very valuable work into its proper position.

Messrs. Hoffmann and Power's very elegant work is evidently not adapted to an ordinary chemical laboratory. As the authors state, it has been prepared for the pharmacist and dispensing practitioner of medicine, for the purpose of enabling him to test chemicals and drugs used in pharmacy. The arrangement of the work is

therefore such as to suit the practical pharmacist rather than the analytical chemist. The substances are described under their several Latin synonyms, in addition to the French, German, English, and Spanish names. We find that each preparation is described as to physical and chemical properties, and then follows a very elaborate examination for the presence of impurities, in addition to methods of quantitative determination of the principal constituents. It should be a very useful addition to the pharmaceutical laboratory.

Mr. Scott-White's volume is one of the usual little books of chemical analysis tables. There seems to be nothing very remarkable about it, excepting the variety of types in which the formulæ are printed. The book, which is intended as a text-book for the various examinations of the University of London, Oxford and Cambridge Senior Locals, and the Kensington examinations, seems well adapted for its purpose. It contains a table of solubilities of common inorganic salts, which is a thing students rarely make use of; and an appendix of requirements in examinations, detailing apparatus, chemicals, &c., necessary for most of the elementary examinations in chemistry.

With all our science classes and the very general spread of scientific education throughout the country, it is still a sad fact that the great mass of the public and even of the middle-class educated public are wofully ignorant on common things. Even now it is somewhat out of place to talk in a drawing-room about oxygen: as to the mention of phosphorus or selenium, or metals like platinum or iridium, it is still more out of place. A great deal of this ignorance—ignorance possibly occasioned by dread—is doubtless caused by the very scientific science books that are in common use. We are almost entirely without books on general science that are sufficiently simple, and at the same time accurate, to convey a general but correct notion of ordinary substances, or to interest the ordinary reader in all these things around us. Why should not the properties of oxygen or phosphorus be quite as interesting reading as some of the three-volume novels? Mr. Lloyd Morgan in his very small book has evidently intended to supply to some extent this want by describing—not in simplest language, it might have been simpler—a few very common chemical and physical facts. It does not appear exactly from the preface for what class of readers it is intended, but it can scarcely fail to be useful if not interesting to any lay readers. It commences with the chemistry of a candle flame, and in that way passes on to the similar actions taking place in animals and plants, where of course carbonic acid comes into play, and we are led through carbonic acid to wood, coal, and diamonds, to the atmosphere, where the physical part comes in, the pressure of the atmosphere, the thermometer, and the idea of elements, compounds, and mixtures. Passing on to water, we have the proof of the composition of water, physical properties of water, which leads directly on to the phenomena of heat. Although only consisting of about 150 small pages, we are led up at the end to some chemical reactions, and an appendix on molecules. The whole book is arranged for experimental purposes, although the methods of performing some of the experiments are not given. It has been probably assumed that the experimenter should have conveniences supplied. The appendix on arithmetical questions seems scarcely required in such a work, but, excepting this, it is certainly a step in the right direction to bring a knowledge of common things into a simple and understandable shape.

"L. M. C.'s" text-book is a sort of chemical, physiological, and biological book, and is divided under the following heads:—Food, its composition and nutritive value; its functions; and its preparation and treatment. It is evidently got up for the purpose of preparing for the examinations, as it says in the introduction that a grant of 4*s*. will be given for a pass, and that payment upon the results of examinations of school children are made to managers. In spite of this a considerable amount of useful information may be obtained from it, although that information is not conveyed in the best possible style. The descriptions of substances like bread, for instance, are not by any means exhaustive. Under animal food or flesh, it is stated that "animal food is composed of the same materials as vegetable; it is formed of the same elements and presents the same approximate principles, and contains water and mineral matters of the same kind as plants." This is not very instructive. The section on food and its selection will be useful, but the main object of the book is evidently to prepare for the examinations on this subject.

If the spread of chemical teaching may be measured by the number of small books on qualitative analysis, it certainly has a great number of disciples. There is nothing very extraordinary in Mr. Stoddard's book, unless it be the importance that is given to the atomicity marks attached to the signs of the elements. We find that iron is described as Fe^{II} and also Fe^{IIII}, whilst chromium is only put down as Cr^{IIII}. Nickel and cobalt are both marked as dyad and tetrad. Only the so-called ordinary elements and acids are treated of.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Reply to Mr. Grubb's Criticisms on the Equatorial Coudé of the Paris Observatory

In continuation of my first letter I now wish, in my turn, to criticise Mr. Grubb's instrument, and to show that in all respects it bristles with inconveniences. I discuss it as it is presented and explained by Mr. Grubb, and I wish to examine it successively—

(1) From the optical point of view.
(2) From the point of view of the mechanism employed.
(3) From the point of view of its application to astronomy.

(1) The optical point of view. The system adopted by Mr. Grubb is much inferior to that generally used in ordinary equatorials. The dialytic telescope only gives images free from colour for the point which lies in the axis of the object-glass. For all other points images present themselves under the form of spectra which are longer as they are further from the axis. This arrangement necessitates that the three lenses must be very exactly centred, which can be done with the ordinary achromatic object-glass where the two lenses are in contact in the same cell. It is with very great difficulty that this can be done in a dialytic telescope. While admitting, however, that it can have an optical axis common for all the lenses of which it is composed, this centering becomes very difficult when the images are broken by a plane mirror, the

angle of which varies, and it becomes almost impossible in a broken equatorial, in which the eyepiece is independent of the moving part of the instrument, as proposed by Mr. Grubb. In a word, taking no account of the new and very grave causes of variability introduced by Mr. Grubb, this optical system is so unstable that its employment has been rejected unanimously by all astronomers and opticians. The least derangement of the position in the central mirror spoils everything.

The mobility of the plane mirror presents equally, from the optical point of view, a slight inconvenience. The quantity of light varies with the different angles of inclination, which renders the exact researches of the photometric very difficult. Without making one feel all its gravity, Mr. Grubb has, in truth, indicated the defect of this optical system. But in order to turn the difficulty he suggests that, since the field of view becomes smaller as the instruments become larger, we may content ourselves with observing at a central point. · But this is an affirmation pure and simple. It is necessary in many measures of precision to have a large field of view. The contrary will present several serious objections. We have, in fact, to observe stars in relation with other stars, to measure, for instance, the difference of declination between a planet and a star of comparison. But we cannot make both these observations at the centre. The same thing will always be happening, in the case of comets, nebula, and clusters. It seems to me, on the contrary, that a telescope is more perfect the larger the field of view. Feeling thus, I have had made by Prazmowski, for my new equatorial *coudé*, achromatic eyepieces giving a very large field. For the observation of comets I have such an eyepiece, which magnifies fifty times and has a field of view such that I can observe a degree. For a telescope of twenty-seven inches we might have such an eyepiece with a field of twenty-four minutes.

From all which precedes, I think everybody will agree that the system proposed by Mr. Grubb is far inferior to that now employed in ordinary equatorials.

(2) The mechanical point of view. The instrument consists actually of an ordinary equatorial, in which the part which carries the eyepiece is replaced by a counterpoise. It presents therefore, from the point of view of stability, all the defects of the ordinary instrument. Additional causes of instability inherent to the design are—

The micrometer and eyepiece are completely independent of the principal mass, which necessarily gives rise to different defects of decentering between the separated parts. Moreover, in this instrument there are three distinct movements. In addition to declination and right ascension, there is a third, which consists of a differential movement round the axis of the mirror. This last one constitutes alone, from the point of view of stability, a complication which does not exist in the ordinary instruments. All the movements of transmission are broken at a right angle, and are four times as long as those of an equatorial *coudé* of the same size. There will therefore be such loss in transmission, one would never have the instrument perfectly adjusted and oriented. We see, from the mechanical point of view, there is such an incoherence between the different parts of the apparatus, that it is inferior to those now employed. And it really cannot be compared with mine, which is almost as stable as a transit instrument, and in which the movements of transmission are excessively simple.

(3) If we examine Mr. Grubb's instrument from an astronomical point of view, we see it is based on a principle which no astronomer can admit, namely, that it is superfluous to observe the greater part of the northern heavens. In many investigations among the most elevated in the astronomy of precision —let us take stellar parallax as an example—one is obliged to combine observations made at different epochs of the year, and it is only by the combination of measures thus obtained that the desired result is arrived at. These stars must be observed, therefore, in the northern part of the heavens as well as in the others, for the vicissitudes of climate do not permit the astronomer to observe exactly how and when he wants. The same necessity presents itself in the study of the double stars; to ascertain and to discard the systematical errors in the angles of position the astronomer is obliged to observe these stars in all the celestial regions. If one wishes to limit one's self to the exploration of one side of the heavens, one would lose precious opportunities and gratuitously introduce serious difficulties. There are also many cases in which this choice is not possible. Thus, if we wish to discover new comets every part of the heavens must be explored, and if one wishes to observe them they must be observed where they are.

Finally, permit me to ask Mr. Grubb how he is going to study that part of the heavens which lies between 20° from the zenith and the Pole. This region of space, I take it, would be entirely closed to the observer with Mr. Grubb's arrangement. Any research, therefore, which touched the stars covering this large area could not be undertaken.

The independence of the micrometer of the rest of the instrument renders impossible any measures of precision. The orientation of the micrometer, in fact, is the fundamental base of every measure, and to do this preliminary work properly three or four successive operations have to be performed, and take the mean of the readings and adjust the apparatus by means of the circle of position. But this fundamental operation cannot be performed on Mr. Grubb's instrument. In fact, in practice, if one wished to take an angular measurement with this instrument, one would have to proceed somewhat in this wise: First of all it would be necessary to content one's self with one approximation as to the orientation; then to repeat this after every individual measure; and lastly to take into account the disorientation of the micrometer, to submit the readings of the circle of position obtained to fastidious computations with a view to compensate them. This gives an idea of all the inextricable complications in which one would find one's self involved in this case. In fact, to secure a simple observation of a comet it would be necessary to increase the readings and the calculation by four times, and after all one would only get a result inferior to that furnished by an ordinary equatorial. I don't believe there is a single astronomer in the wide world who would undertake observations of precision under such conditions.

It is quite true, as Mr. Grubb indicates, that the *oculaire* might be connected with the rest of the instrument, but then, new inconveniences of another order would arise. These, however, I will not discuss now, for, as I said at the beginning, Mr. Grubb's actual proposal is now alone in question. However this may be, I consider the conception of this equatorial is so defective, taken as a whole, that I do not think its adoption would be seriously recommended. Nor do I think that the project will go beyond its present stage, unless essential modifications are introduced, and in this case the instrument would become like my own.

Paris Observatory M. LŒWY

Dust-Free Spaces

I VENTURE to call attention to some points in connection with the observations on "dustless spaces," &c., as detailed in the report of Dr. Lodge's lecture published in NATURE, vol. xxix. p. 610.

Certain observations and studies of my own lead me to think that, if attention be given to the points to which I wish to call the notice of physicists, results of the highest importance may be reached by means of the method of experimenting developed by Dr. Lodge and Mr. Clark, and described in the report referred to.

Dr. Lodge's statement (p. 611) that "cloud spherules are falling, but falling very slowly," is true when these spherules are not at a higher temperature than the atmosphere in their neighbourhood. When, however, very small particles floating in the air become heated, they warm the air immediately surrounding them, and then these particles are either buoyed up by a small envelope of heated and dilated air clinging to their surfaces, or they are borne aloft by the local currents which they create by contact with the surrounding atmosphere.

Observations continued for nearly fourteen years have convinced me that in ordinary clouds these two methods of lifting are combined—that to a certain extent each of the spherules or very many of the spherules of clouds are buoyed by adherent heated and dilated air, and that the whole of the cloud, in many cases at least, becomes warmer than its neighbourhood in general, which adds to its buoyancy as a mass of intermingled air, water, and vapour.

These remarks apply also to small particles of matter other than water. The action is the same except in degree. The very high specific heat of water enables it to heat surrounding air more readily and quickly than other substances do, and as a consequence masses of water as in clouds are lifted more quickly and to a greater height than masses of other bodies having the same proportion of surface to weight.

If it be remembered that radiant heat passes uninterruptedly through air, *i.e.* that air is diathermous, it will be seen that radiations from a distance striking upon particles of athermanous bodies suspended in the air will cause these latter to heat the

air about them, and produce upward currents or a buoying of the athermanous particles by dilation of the air in contact with them.

This affords a complete explanation of cloud-flotation and the flotation of fine dust-particles. For some years I have been in the habit of watching clouds, and by the use of the above theory have very often been able to account for forms, dimensions, and movements which I could not otherwise explain. Some fours ago I explained the above ideas to the Chief Meteorological Officer of the United States Signal Service, and received from him suggestions which have since afforded me the means of much pleasure in observing the locations and forms and movements of clouds, and although these irregular masses are subject to many complicating circumstances, I have never yet observed anything tending to weaken this theory of flotation, but have made many hundreds of observations tending to confirm it.

I trust that it will be taken for granted that I do not wish to attack the hypothesis of Dr. Lodge and Mr. Clark, that heated bodies "bombard" and drive away approaching particles. My object is simply to show that, as it seems to me, the theory of particles buoyed up by a locally heated fluid, when considered in connection with well-known principles of radiation, &c., is sufficient to account for the phenomenon of the "dust-free coat" described in the article alluded to.

Referring to the figures on p. 612, an ascending current is shown in the neighbourhood of the pipe or rod in Fig. 1. The theory which I have sketched would indicate that this current had been set up in great measure by the *indirect* action of the heated tube or rod upon the surrounding air.

I should contend that the dust-free coat may be explained as follows:—

A given particle which may be assumed to be directly below the rod is heated by radiation from the rod. It in turn heats and expands the air in contact with it; the particle with a coat of adherent air becomes lighter than the surrounding atmosphere, and the mote, with its jacket of expanded air, ascends towards the rod. As it reaches the point marked "slow moving" in the figure, it begins to find itself in air which has been heated directly by contact with the rod, and distributed near it by the small "circular" currents which always surround a blunt obstacle in a stream of fluid. At the outer limit of the "dust-free coat" the particle or mote is arrested because it has come to a point where the air is so warm that the mote can no longer heat its jacket enough hotter than its surroundings to cause buoyancy. It is arrested because it has reached a point where the surrounding medium is as light as its own air-float, much as cork is arrested at a surface of water.

The mote with its warm air jacket could ascend through cool and therefore heavy air, but the air warmed by contact with the pipe is too light to float it.

The dark "tail" above the rod, or tube, is the upstreaming dust-free air, warmed by the tube, and too light to carry motes, or in which motes have not been carried by any current.

The report of the lecture contains within itself some very striking confirmations of this theory. For example, Dr. Lodge tells us that at a high temperature the dust-free coat is thicker than at low ones. This is according to the theory of flotation as above set forth, because an approaching mote would sooner meet the increased body of air warmed by contact with the tube to a point sufficient to destroy the buoyancy of the mote and its jacket. Again, hydrogen is a light gas having a very high specific heat; hence according to this theory the mote would need more heat and more difference of temperature to float than in air, and consequently should not be able to float up to as near the rod. Now, Dr. Lodge states that "in hydrogen it [the dust-free coat] is thicker than in air." With a surrounding medium of carbonic acid, less heat and less flotation are required for the mote, as the gas is heavier and of lower specific heat, and, quite in accord with the theory, the dust-free coat "is thinner" than in air or hydrogen. Again, Dr. Lodge states that the dust-free coat is set up by a "difference of a degree or two," and it would apparently require a much more complicated theory than the simple one here advanced to account for this on the bombardment hypothesis, as the action has been shown to be—

(1) Affected by the medium as to thickness of coat.

(2) Obtainable at different temperatures in the rod.

(3) Apparently dependent, not on the actual temperature of the rod, but on the differences in temperature between the rod and its surrounding dust-containing fluid.

The behaviour of cool rods or plates, as stated, is also in accord with this theory. A mote coming within the influence of the plate or rod is cooled by radiation and loses buoyancy in its air jacket. If above the plate, it therefore falls upon it; if below, it drops away. Dr. Lodge does not explain how a cool plate "bombards" the motes and drives them away from its lower side. If clearly explained, the method of experiment developed and now under study by Dr. Lodge and Mr. Clark, and that of Mr. Aitken on the condensation of water about nuclei, will probably be found productive of results of the very highest importance.

Questions of climate, rainfall, healthfulness of districts, fogs, mists, humidity, &c., can probably be better studied than in any other way by some form of apparatus based upon results obtained by these experiments, if the theory of flotation above set forth is connected with them, as I trust it may be.

EDW. W. SERRELL, Jun.

Chabeuil, Drôme, France, April 27

Mr. Serrell is no doubt perfectly correct in his view that the average specific gravity of a warmed and vapour-filled cloud may be often less than that of air. The ascent of the so-called "steam" from a kettle proves this, and he will find the view clearly stated in Maxwell's "Heat," p. 280. I did not enter into details in the Dublin lecture, but I was fully convinced of the truth of this statement.

His supposition that the dusty air near a hot body gets warmed not by gaseous conduction from the hot body but by interception of its radiation by the suspended particles, is not an unnatural one, but it is practically untrue. It is disproved by the fact that the concentrated radiation from the electric light is much less effective in warming dusty (or any other) air, than is the neighbourhood of a warm solid only a few degrees above the atmospheric temperature.

Mr. Serrell's criticism, that we do not clearly explain the down-streaming dark plane from a cool body observed by Lord Rayleigh, is quite legitimate. So far as I entered into the matter at all, I intended to indicate provisionally a distinction between a cool body and a very cold one—the boundary coming somewhere, say, between ten and thirty degrees below the air, or possibly depending upon actual temperature as well as on difference. I am not prepared to assert that the bombardment of particles towards a cool body begins the instant it is colder than the atmosphere. I think it possible that there may be a neutral point below which it begins.

But Mr. Clark is working out this among many other points, and I am not sure that his view at present agrees with my hypothesis. He will doubtless make a complete statement when he publishes an account of the quantitative research he is now engaged in. Till then I prefer to leave the account of cold bodies a little vague.

O. J. LODGE

The Supposed Volcanic Dust Phenomena

THE reddish circle round the sun, which I suppose must be considered as a kind of very large corona, alluded to by E. Divers of Tokio (NATURE, vol. xxix. p. 283), G. F. Burder (p. 525), and other observers, was invariably visible here, when circumstances favoured, from November 1883 up to April 3. In the middle of that day, and of the 4th, though circumstances seemed favourable for seeing it, no tinge of red was perceptible; but it was visible late in the afternoon of the 4th. Since then it has become more visible again, and from April 21 has been very plain, though not so conspicuous as it was originally. It is red in the middle of the day, and brown towards sunset, the bright space between it and the sun being blue or greenish.

The semicircle opposite the sun is now far fainter than it was originally, indeed I do not think I should notice it now without looking for it. It is now plainest when the sun is a little above the horizon, which was not formerly the case, and I have not seen it after sunset lately. This may perhaps be owing to a change in the height of the volcanic dust, or whatever it is.

The amount of sediment in the rain strikes me as being very large. I have at different times in the last few months collected it upon glass and examined it with the microscope: there appear in it a considerable variety of crystals and other transparent objects. Some of the crystals are like those drawn by Mr. Beyerinck (vol. xxix. p. 309). I have usually found a number [illegible]regular transparent pieces, but I cannot say that they have

much resemblance to the vitreous ashes of Krakatoa, drawn on p. 587, as they are very thin.

I have examined this sediment with the naked eye to see whether I could perceive anything like the large corona. I darkened the room and admitted the sunlight through a narrow slit on to the glass. The sediment sparkles with various colours, chiefly pink and green, I suppose owing to interference; and it is difficult to judge which colour preponderates. I find a decided excess of green at a small angular distance from the sun, and often pink preponderates at a greater but varying distance. These colours being similar to those seen in the large corona are slightly confirmatory of the theory that the sediment from the rain is the substance which has caused it and the strange sunsets and sunrises; but other substances are also capable of giving a green light near the sun. Moisture on glass gives quite different colours, so far as I have observed.

The cirrus-like wisps on which the sunset phenomena appeared were definite and very small at the end of November; but on the whole grew larger and more indefinite, till at length they have been quite imperceptible for several weeks past.

On April 24 there was the first moderately bright aurora I have seen since October 5. Can this remarkable absence of auroras and the scarcely less remarkable frequency of lightning have been caused by the volcanic dust? If so, it may also account for S. Tromholt's finding auroras so scarce and poor in Iceland during the winter, as mentioned on p. 537 (vol. xxix.) though he does not say whether they were scarcer than usual there. THOS. WM. BACKHOUSE

Sunderland, May 10

Pons' Comet

PONS' comet was visible here with the naked eye throughout the month of February, including the nights of greatest moonlight. I so saw it on some twenty or more nights during that month, and append some notes as to its comparative brightness, so far as I could judge.

February 3.—"Comet visible till 10.45. Could see 'old moon' with naked eye easily, and in telescope Grimaldi and Aristarchus, but only with a very small part of sunlighted portion in field."

February 6.—"At 8.45 could see comet with naked eye, though sky not quite free of sunset-glow and somewhat hazy, and moon nine days old. It was altogether faint, but most of the tail visible at other times could be seen—certainly more than I should have expected."

February 9.—"At 9.30 found the comet with naked eye and could see it without difficulty, but there was only the suggestion of a tail. Comparing it with α Sculptoris by looking midway between the two, they produced the same effect on the eye; but of course the least magnifying power showed the difference."

February 10.—"8.20 to 8.50. Found comet with naked eye, but it was very faint, and to the unaided eye looked certainly fainter than α Sculptoris. Yet it seemed to me that more of the tail (or the tail more certainly) was visible than last night."

February 11.—"Found comet with naked eye about 8.10, and watched it up to 9.40. As the sky lost the traces of sunset I could pick it up without difficulty, in spite of the full moon shining in a cloudless sky. It was not quite so easily seen as α Sculptoris, but I may say that λ^1 and λ^2 Sculptoris, though each marked as of the same magnitude as α, I could not get a glimpse of, though I tried hard."

February 12.—"At 8.15 found comet with naked eye without difficulty, and so at intervals up to 9. Found it again with difficulty at 10.15; it was then getting low and into the haze: in the telescope it seemed then to have lost (at a guess) half its light."

On the subsequent clear nights in February there was no difficulty.

March has been much cloudier, and owing to this and moonlight I only saw it with naked eye certainly on four nights—the 1st, 4th, 16th, and 17th. My note for the 4th is: "Found and saw comet with naked eye several times, though not easily, between 8.15 and 8.40 p.m. Could see the outline of the 'old moon' without difficulty."

The 5th is marked as doubtful both as to comet and "old moon."

March 14.—"A fine pink glow in evening, and splendid afterglow about 7.15—never saw it better. Found comet easily with opera-glass, but could not see it with naked eye, the moon rising before the glow had vanished." So also on the 15th.

March 16.—"Saw comet repeatedly with naked eye (looking a little above it) between 7.45 and 8.30. Sky very good."

March 17, 7.40 to 8.10.—"Found comet with naked eye, and saw it many times, looking a little above it; could not be quite sure of seeing it direct."

Owing to clouds I have only seen it on two nights since, the 24th and 28th; and that only with opera-glass and telescope.

Snow and Ice Flora

IN the account of Prof. Veit Brecher Wittrock's interesting work on the Arctic snow and ice flora (NATURE, vol. xxviii. p. 304) your reviewer enumerates the countries and mountain ranges where red snow has been observed, but does not mention the Southern Alps of New Zealand, where as far back as 1861 this plant was observed by me. The fact that green and red ice have been found in these high northern latitudes, and that the unusual coloration has been traced to microscopic organic life is of special interest to me, as I repeatedly observed green as well as red ice amongst the glaciers of New Zealand, first at the head of the Rangitata River, as far back as February, 1861. At the time I published an account of this occurrence, which was reprinted by others (amongst others see Hochstetter's "Neu Seeland," 1863, p. 342). Since then during my alpine explorations I have repeatedly observed the same phenomenon, so that evidently at the Antipodes there occurs a counterpart of the Arctic snow and ice flora. It is to be hoped that some able botanist will some day do the same work for us that Baron Nordenskjöld and his able coadjutors have done for Greenland and Spitzbergen. JULIUS VON HAAST

Christchurch, N.Z., December 31, 1883

The Rotation Period of Mars

NOTWITHSTANDING his comparatively small diameter and slow axial motion, the planet Mars affords special facilities for the exact determination of the rotation period. Indeed no other planet appears to be so favourably circumstanced in this respect, for the chief markings on Mars have been perceptible with the same definiteness of outline and characteristics of form through many succeeding generations, whereas the features such as we discern on the other planets are either temporary atmospheric phenomena or rendered so indistinct by unfavourable conditions as to defy lengthened observation. Moreover it may be taken for granted that the features of Mars are permanent objects on the actual surface of the planet, whereas the markings displayed by our telescopes on some of the other planetary members of our system are mere effects of atmospheric changes which, though visible for several years and showing well-defined periods of rotation, cannot be accepted as affording the true periods. The behaviour of the red spot on Jupiter may closely intimate the actual motion of the sphere of that planet, but markings of such variable unstable character can hardly exhibit an exact conformity of motion with the surface upon which they are seen to be projected. With respect to Mars the case is entirely different. No substantial changes in the most conspicuous features have been detected since they were first confronted with telescopic power, and we do not anticipate that in future ages there will be any material difference in their general configurations. The same markings which were indistinctly revealed to the eyes of Fontana and Huyghens in 1636 and 1659, will continue to be displayed to the astronomers of succeeding generations, though with greater fulness and perspicuity owing to improved means. True there may possibly be variations in progress as regards some of the minor features, for it has been suggested that the visibility of certain spots have varied in a manner which cannot be satisfactorily accounted for on ordinary grounds. These may possibly be due to atmospheric effects on the planet itself, but in many cases the alleged variations have doubtless been more imaginary than real. The changes in our own climate are so rapid and striking, and occasion such abnormal appearances in celestial objects that we are frequently led to infer actual changes where none have taken place; in fact, observers cannot be too careful to consider the origin of such differences and to look nearer home for some of the discordances which may have become apparent in their results.

The rotation period of Mars has been already given with so much precision that it may seem superfluous to rediscuss the point, but it is very advisable to see whether recent observations

confirm the values derived from former results. The "Hourglass" or "Kaiser Sea," which is admittedly the most prominent mark on the planet, is a very suitable one for comparisons to find the intervals of rotation. Early in 1869 I saw it with a 4¼-inch refractor as it passed the central part of the disk. On February 2, 1869, it was central at 10h., on February 4 at 11h., and on February 5 at 11h. 30m.

I observed the same object in February of the present year with a 10-inch reflector (power 252), and noted it crossing the planet's central region at the following times:—

1884		h.	m.
February 14	... ...	5	55
15	... ...	6	35
19	... ...	9	5
22	... ...	11	4

I have combined my observation of February 4, 1869, with that of February 14, 1884 (as I regard this pair as the best obtained), to ascertain the rotation period. The interval includes 5487d. 18h. 55m. = 474,144,900 seconds. Correcting this for the difference in longitude between Mars and the earth at the two epochs and for defect of illumination (there is no necessity to apply any correction for equation of light, as the apparent diameter of the planet on the dates selected for comparison was about 16", and hence the distances were nearly the same), I find the time of rotation resulting from the discussion of these observations to be

h. m. s.
24 37 22·34 (5349 rotations),

which is in satisfactory agreement with the periods computed by Kaiser, Schmidt, and Proctor from a much longer series of observations. In order to exhibit the small differences between the period now computed and those resulting from some of the best modern determinations, I give the following summary:—

	h.	m.	s.	
J. H. Mädler ...	24	37	23·8	*Ast. Nach.* 349.
1864, F. Kaiser... ...	24	37	22·62	*Ast. Nach.* 1468.
1866, R. Wolf	24	37	22·9	*Ast. Nach.* 1623.
1869, R. A. Proctor ...	24	37	22·735	*Mon. Not.* vol. xxix. p. 232.
1873, F. Kaiser	24	37	22·591	*Annalen der Leidener Sternwarte*, vol. iii. p. 80.
1873, J. F. J. Schmidt	24	37	22·57	*Ast. Nach.* 1965.
1884, W. F. Denning	24	37	22·34	

It is obvious that Mädler's period of 24h. 37m. 23·8s. is about one second too great. If we take a mean of the other six values (all within 0·6s. of each other) we get

h. m. s.
24 37 22·626

which may be fairly regarded as a very near approximation to the true sidereal rotation period of Mars.

The computations of Kaiser, Schmidt, and Proctor are severally based on very long periods, the comparisons being modern observations with those of either Huyghens or Hooke during the last half of the seventeenth century. It is unfortunate, however, that there is some question as to the correct identification of the spots depicted in some of the ancient drawings. The representations by Hooke on March 2, 1666 (old style), at 12h. 20m. and 12h. 30m., also those by Huyghens in 1659, 1672, and 1683 give a large irregular spot, extending in a north and south direction, which can only be identified as the "Hourglass" or "Kaiser Sea." It would appear, however, that this interpretation is incorrect in certain cases, for the several drawings do not only show disagreements with each other but also when compared with modern observations originate discordances of period, small it is true, but still too large to be attributed to simple errors of observation. No doubt the period which approaches nearest to the truth will become apparent from future observations, though it can hardly admit of definite settlement for many years, inasmuch as the differences between the several times of rotation as above deduced are very insignificant, and must so closely accord with the real period of the planet that the errors such as exist must be allowed to accumulate over a lengthened interval before they will become distinctly manifested. A comparison extending over fifteen years is insufficient for the purpose, for a computed time of rotation, erroneous to the extent of one-tenth of a second, will still, at the termination of such a period, answer to the positions of the markings to within 9 minutes of time. It is to be remarked that Mr. Marth, whose opinion is entitled to great weight, has, for some time, adopted the period of 24h. 37m. 22·626s. for the rotation of Mars. This corresponds to a daily rate of 350°·8922, and forms the basis of his computations in his "Ephemerides for Physical Observations of Mars," annually published in the *Monthly Notices*.

W. F. DENNING

"The Electrical Resistance of the Human Body"

WILL you kindly publish the inclosed from Prof. Dolbear? It furnishes a complete explanation of the discrepancy between his measurements of the resistance of the human body and those which I have recently made. At the same time, as I have pointed out to him, the fact that this resistance may sink below 500 ohms with "soaked skin," even if that be "abnormal," is of the highest physiological importance, and goes far to explain the hitherto mysterious deaths from accidental passage of a current through the body. Most of these, as Prof. Forbes remarked to me, have taken place with alternate, not continuous, current machines.

W. H. STONE

Wandsworth, May 11

College Hill, Mass., April 23, 1884

DEAR SIR,—I have to acknowledge the receipt of your pamphlet "On the Resistance of the Human Body," for which I am obliged. I am glad to know that physiology has some one in its ranks who is interested in that line of work, and who knows what to do in order to settle such vexed questions.

I have also seen in the last *Electrical Review* that has reached me an article on the same matter, in which you refer to me and what has been published concerning some of my work, that needs a little elucidation. In the early days of telephony the experiment was often tried of making the human body part of the circuit in order to see how speech could be transmitted through the body, in the language of those days. Bell wanted to know what the resistance of the body was when in such circumstances, and I measured it from hand to hand when thumbs and fingers grasped the terminals of a wire and found it to vary between 6000 and 15,000 ohms, and wrote to him to that effect, and from that grew out the statement to which you have referred. Now *under such conditions* that work is right, as I have frequently since proved.

It seems to me that when we speak of the resistance of the body or of any body, and do not define what is meant by body, it is fair to assume that the body is the ordinary body under ordinary conditions. If the resistance (the *actual*) of the wire is found to be a thousand ohms by one party and another one files off the rust from the contacts and then finds the resistance less, both parties may be right. Now the skin of individuals is more or less horny in texture, and so has high resistance which soaking may reduce, and the question then properly arises, is the hard skin properly a part of the body? The resistance of a farmer's hand is often twice as great as that of a child's or of a man of sedentary habits, but solely, as I think, because of the thickness and density of his skin. Does not the question resolve itself into this—What is the resistance of a dry hand and the resistance of a soaked hand? What is the resistance of a good conductor and the resistance of a poor conductor? If the poor one is made better in any way, its resistance is correspondingly increased.

If the condition of the body is abnormal, its resistance may also be abnormal. I should call a soaked skin abnormal.

Still it is of the utmost importance that we should know what the resistance is under all conditions, as being the only way to advance in knowledge of the physiological effects of known currents, and I would again express my gratification at your persistent work in this field, and if I can in any way be of service to you I shall be pleased to be employed.

Yours very truly,

To Dr. W. H. Stone A. E. DOLBEAR

Instinct in Birds

MR. GRAVES, who writes on this subject (NATURE, vol. xxix. p. 596), is, I fear, not so accurate an observer as the magpie, for he misquotes the day fixed by the birds for building, and then indicates that the young "mags" are restricted to four in each nest, while the fact is there are often six or seven in a nest. The magpie is too fond of a fresh egg for breakfast to escape the attention of the gamekeeper. I have often seen the greater part of their nest shot down, repaired, and reoccupied by the birds year after year. I know of no bird that begins the work of *nidification* here early in February, nor any that devotes two months to the work. The rook (*Corvus frugilegus*) is the first to

begin, and I have often been told that it does so early on the first Sunday of March, G.M.T.

What I said about the magpie beginning on the first Sunday (old style) was founded partly on report, but mainly on personal observation extending over some years at one breeding-place, where I have often seen them at work for the first time on this particular morning, and on one occasion in another locality on the same day.

This instinct is not confined to any particular tribe or order, but is common, I think, to all wild fowl, and the two instances given by Dr. Rae (vol. xxx. p. 7) of the regularity with which certain birds pass north to their breeding-grounds is precisely the point at issue, as I believe they begin work as soon as they arrive.

Scientific accuracy has not yet been directed to the subject, but there can be no doubt that from some cause, possibly a sharper and better defined division of summer and winter in former ages, all the feathered tribe have inherited an instinct in nest-building and in the time of their arrival at and departure from their breeding-grounds which guides them to a day in many cases without reference to the state of the weather.

Watts's "Inorganic Chemistry"

THE review of my "Inorganic Chemistry" in NATURE of May 1 (p. 3) appears to have been written without much knowledge of the previous history of the work. The reviewer, indeed, writes as if he were criticising an entirely new book, whereas a glance at the preface might have shown him that the volume in question is the first part of the thirteenth edition of Fownes's well-known "Manual of Chemistry," the first edition of which was published in 1844.

H. WATTS

The Recent Earthquake

I NOTICE that Mr. Topley, at the conclusion of his communication to you respecting the recent earthquake in Essex, remarks, "but at present we know of no observations in the central parts of Kent, Surrey, or Sussex." I wish therefore to mention, that although I did not myself notice anything in connection therewith, yet an invalid neighbour of mine, lying in bed, distinctly heard a rumbling noise about 9h. 20m., and a moment afterwards perceived some pot plants in front of his window sway to and fro. This is the only incident with which I have been made acquainted.

C. L. PRINCE

The Observatory, Crowborough, Sussex, May 3

THE rise in the Essex waters detailed in my letter of last week still continues. Mr. Radforde Sharpe has kindly sent me the following additional heights that the water rises from Messrs. Courtauld and Co.'s well, at Bocking, Braintree, in inches above the surface of the ground:—

May 6	40½ inches	May 9	39½ inches
,, 7	38½ ,,	,, 10	39¾ ,,
8	40	12	44

At Colchester Corporation Waterworks Mr. C. Clegg, C.E., reports the rise recorded is still maintained.

Museum, Jermyn Street, S.W. C. E. DE RANCE

W. H. FRANCE.—Any good entomological text-book will give you the information you ask for.

NOTES ON EARTHWORMS

EVER since our great naturalist called attention to the common earthworm, we watch them with entirely different eyes as they creep timidly out on to the lawn or hurry across the gravel walk; as they collect the dead leaves or bits of string and cloth we may have dropped the evening before, or heap up their household refuse outside the entrance to their home.

He long ago pointed out its importance as a geological agent. The surface of the ground would be very different were it not that the earthworm is for ever at work bringing in the decaying vegetation and converting it into mould. And, more than this, the superficial deposits are often modified to a considerable depth by the earthworms, which, carrying the earth mouthful by mouthful, and the gravel stone by stone, invert the order of stratification.

But we must not push this explanation of the origin of the universal surface mould too far. I received one caution from Darwin himself, many years ago when I was talking to him about the manner in which the chalk with which the land was dressed in Kent worked down. He told me to be careful to bear in mind the action of the great Kentish plough as it year by year turned swathe after swathe down the slopes. The result of this plough-down is clearly distinguishable from worm-mould. In his work on earthworms also he refers to another mould-forming agent of more universal operation and hardly less important cumulative effect. My attention was first directed to it by a lecture I heard delivered by Stoppani in Milan many years ago, in which he was explaining the action of the wind in modifying the surface of the earth, and especially in carrying dust, organic and inorganic. Richthofen and Drew have thus explained the origin of the loam that covers half Asia; and Mr. Clement Reid has recently extended the same kind of observation to Great Britain (*Geol. Mag.*, April 1884). Without this addition we can hardly explain how earthworms could find the material for the manufacture of the mould which often fills the interstices of the ruins of a buried city.

We find, commonly, isolated tumps of moss-covered soil, and every gradation from that up to the large patches of mould which hang like little gardens on each sheltered ledge, where the greater part of the material must evidently have been carried from elsewhere and not have been brought up from below; where it is obvious, from the character of the rocks, that the principal part of the mould cannot have been derived so much from them as from the wind-carried fragments of organic and inorganic material and the decomposition of the vegetation that soon began to grow upon it.

But we find also that the earthworms soon appear in such places, and set to work to mix up and modify all this various stuff that has by various agencies been brought together.

As squirrels, burying acorns and nuts in the autumn, have planted many an oak forest and hazel grove, so it is probable that the earthworms plant many of the ash and sycamore trees that we see perched in out-of-the-way corners, where it is difficult to explain how the blown seed can have got covered by mould enough to allow it to germinate. If an overhanging tree drops the seed, or the wind carries it anywhere near the worm's feeding-ground, it is dragged in and planted in leaf mould, and kept moist till spring time. At this time of the year we see clusters of sycamore seedlings growing up together out of the little worm-hills into which they had been dragged heavy end first.

It is therefore interesting to inquire into the various reasons that should make earthworms travel and occupy new ground. Round the margin of an overcrowded colony we should expect them to spread. They cannot live under water, so they have to move away before a flood. It has been stated that "they may live when completely submerged in water for nearly four months" (Romanes reviewing Darwin, NATURE, vol. xxiv. p. 553). But they were killed off by a flood of a couple of days' duration in the Backs of the Colleges at Cambridge in August 1879. Some of them seem to have got on to the paths, which are raised above the surrounding meadows, and there died. Where the greatest number were found dead the ground had been submerged for a longer time. The following carefully recorded observations by the Rev. Henry Russell, of St. John's College, are worth noting:—

"On Sunday, August 3, 1879, our paddock (the inclosed space in which the men play at lawn tennis, in front of the

new court) was covered with water to the depth, at 1 p.m., when it was greatest, of four to five feet. The level of the paddock is much lower than that of the ground surrounding it. . . . Therefore, on Wednesday, August 6, I cut a trench from the north-west angle of the paddock across the raised path. . . . The water had drained off by Saturday evening, August 9. The rush of water from the west across the Fellows' garden had carried with it into the paddock a great quantity of worms, which, when the water had subsided, were observed, some very large, lying dead under the water. As the water drained off, these lay on the paddock and on the slopes of grass surrounding it, and the smell of them infected the air till Friday, August 15."

Mr. Russell's observations go to show that the worms found dead were not all worms that had lived in the paddock, but those which had got washed out with the earth from the Fellows' gardens, and so they perhaps perished sooner being in the water. It is probable that worms buried deep in the earth under submerged meadows may, if they remain underground, hold out through much longer floods. However I gather that a large number perished in the adjoining parts of the Backs, and were seen on the paths and slopes as soon as the flood began to subside. Many of them were of exceptionally large size. I have heard of land injured by floods where the injury was supposed to be principally due to the destruction of all the earthworms. It is probable that the growth of peat-mosses may be in great part referred to the fact that the conditions were unfavourable to earthworms, for had they been there they would have worked up the vegetable matter into mould.

But there must be something besides floods that makes earthworms migrate.

If we drive a stick into the earth and move it about so as to shake the ground, the earthworms will come out to the surface and scuttle away in all directions. This was a common way of getting worms for fishing, and we used to be told, as Darwin notices, that the worms came out because they thought a mole was digging after them.

There must be however some other reason why worms will often come out to the surface in the daytime, and hurry away across a gravel path or on to a road, and why they then seem so much less sensitive to tremor of the ground about them than do the worms that come out to feed on the lawn.

From the analogy of other more highly organised animals I could not help thinking that there must be some creature that hunted the common earthworm, some worm ferret that drove them out. Many who have passed their lives in the country know well when they see a large field-mouse cantering down a road and showing little fear of man that a fiercer enemy than man is following the poor little animal with untiring certainty. If you draw aside and watch, you will soon see a weasel following by scent. Even a hare or rabbit will at length lie down paralysed with terror, and give itself up to the stoat that has followed it with deadly pertinacity. The sudden appearance of one or two strange birds in a neighbourhood has often been a source of wonderment, and it has sometimes been suggested in explanation that they had been chased by birds of prey and got up into strong currents of air. Those who have seen a peregrine drive a flight of rooks up into the sky can easily see how this might happen. In the cases to which I am referring the earthworm comes out like a hunted thing. I have also noticed that many of the worms that I found dead or torpid were maimed; generally they had their tail cut off, and this when there had been no digging in my garden for a long time, and although there are few birds that would touch them. I have frequently observed that the earthworms were apparently unwilling to go to ground again though I have tried to make them in order to watch the rate and manner in which they buried themselves. A few days ago, however, I saw, I believe, the explanation of most of the cases I had been observing. A large earthworm about nine inches long, bright, clean, and healthy-looking, was moving somewhat irregularly on the earth of a flower-bed. On stooping to examine it, I found a small yellow animal with a brown head holding on within about half an inch of the tail end of the worm. I sent it to Prof. Westwood, who writes: "Your worm-eating larva is evidently one of the Carabidæ, probably *Steropus madidus*" (see *Gardener's Chronicle*, 1854, p. 613). It was not disturbed by my taking up the worm, but went on biting its way round the worm, holding on like a bulldog, and bettering its hold every now and then. It had nearly got round the worm, leaving a lacerated ring. The wounded part seemed somewhat swollen, but on this point I am not clear, as the unequal power of extension of the wounded part may have produced the effect of swelling. Mr. Edwin Laurence has recorded (NATURE, vol. xxvi. p. 549) a similar circumstance observed by him in France, where, however, the larva seems to have attacked the worm differently, and with a view to killing it rather than cutting off a portion, and from his description, moreover, it would not appear to be the larva of the same species. He suggests that the numerous birds in England may have destroyed such an enemy of the earthworm. A sparrow would probably take the larva, and not touch the earthworm. One would have thought that the earthworm would have a better chance of rubbing off his deadly enemy in the earth than above ground, as a salmon is said to clean himself in a gravelly river, but we want further observations on this curious question, as well as on several others raised by the inquiry, How are worms transported to out-of-the-way places? and How long can they live in soils of various degrees of permeability when the surface is flooded?

T. MCKENNY HUGHES

THE LOW BAROMETER OF JANUARY 26, 1884

IN the end of January we gave a brief notice (see NATURE, vol. xxix. p. 316) of the unprecedentedly low barometric readings which were observed on the evening of January 26 in the middle districts of Scotland over which the centre of that great storm passed. The lowest reading, reduced to 32° and sea-level, then given was 27·332 inches, and was observed by Mr. George Croucher at Ochtertyre, near Crieff. This still remains the lowest reading observed during the storm, and as it is absolutely the lowest known to have been observed in Europe, if not indeed the lowest on any land surface of the globe since the invention of the barometer, it is desirable to give an accurate record of it in NATURE.

On that occasion, Mr. Croucher's observations included the barometer, its attached thermometer, and a thermometer hung outside the window, it being too stormy to venture out. The observations near the time of greatest depression, corrected for instrumental errors and reduced to 32° and sea-level, were, in inches, 27·631 at 7 p.m., 27·527 at 7.45 p.m., 27·420 at 8.30 p.m., 27·390 at 9 p.m., 27·332 at 9.45 p.m., and 27·365 at 10.15 p.m. The correctness of these readings is amply attested by the hourly barometric readings made at a considerable number of the Scottish meteorological stations that evening.

At the meeting of the Royal Meteorological Society on February 20, a paper was read on the storm of January 26, in which it is remarked that "the lowest readings of the barometer (reduced to 32° and sea-level) yet reported were 27·32 inches at Kilcreggan, and 27·332 inches at Ochtertyre." The observations at Kilcreggan were made with an aneroid, whose errors were unknown. From the hourly observations made at the different stations in Scotland, the isobars for each hour have been drawn, and, from a comparison of the Kilcreggan observations with these

isobars, the following approximate errors of the aneroid have been determined for the lowest recorded readings:—

p.m.	Aneroid, inches		inch
7	... 27·300	... Approximate error	−0·230
8	... 27·200	... ...	−0·240
8.30	... 27·155	... ...	—
9	... 27·200	... ...	
10	... 27·300	... ...	
		Mean error	−0·230

If the correction + 0·230 inch for instrumental error and height be applied to 27·155 inches, the lowest observed sea-level reading at Kilcreggan was only 27·385 inches—a reading, it may be remarked, agreeing closely with the lowest readings noted at several stations on the mainland and islands of Argyllshire earlier in the evening. The Ochtertyre reading, 27·332, was thus, so far as known, absolutely the lowest recorded during the great storm of January 26, 1884.

THE THEORY OF SUNSPOTS[1]

THE literature of heliography, by no means inconsiderable in extent, has received an addition by the publication of the work before us which, if it makes no attempt to enlarge our knowledge of solar phenomena from personal observation, is deserving of notice as a specimen of one of the modes in which those phenomena are attempted to be explained.

The subject is confessedly full of difficulty as well as interest. Nothing can be more natural than the wish to obtain some knowledge of the constitution of that splendid orb that is the dispenser of life and enjoyment to unnumbered millions of organised beings, and that exhibits on its surface such a strange development of forces commensurate in intensity with its amazing magnitude. But these tempting inquiries are beset with difficulties scarcely to be appreciated in the absence of actual experience. When we bear in mind the amount of light and heat that has to be encountered, with all its consequences in optical, mechanical, and atmospheric impediments, we may rather wonder that man should have been permitted to accomplish so much, than that he should have failed in effecting more. The serviceable working of the telescope soon comes to an end; and what it is able to exhibit it is not able to render intelligible. In strong contrast with the exploration of the selenographer, who feels no doubt as to the general character of his object, whatever perplexities may arise out of the study of its details, the observer of the solar disk knows absolutely nothing as to what he is looking upon. He finds a blazing surface of by no means uniform texture, unlike anything else in the whole compass of his experience. He encounters strange-looking specks that disfigure, if we might venture to use such a word without presumption, the purity and perfection of that brilliant orb. In those dark patches, and their attendant fringe-like borders, what is it that meets the eye? Cavity? or cloud? or eruption? or cyclone? or scoria? Have astronomers succeeded in explaining them? Shall we listen to Wilson, or Herschel, or Kirchhoff, or Nasmyth, or Secchi, or Faye, or Zöllner, or Langley? More or less, they all disagree. Or shall we be venturous enough to attempt an independent solution of the mystery? Little encouragement could be found in such a course. After such protracted discussion we could hardly bring to our telescope an unbiased eye or an impartial judgment. What we are looking for, we should be likely to find. We shall be surrounded with phenomena that lend themselves with perplexing facility to very dissimilar and even opposite interpretations; and, where one observer is confident as to a clear vacancy leading down to unimaginable depths, another fills the same dark area with heavy clouds or floating dross. There may be, and for our own part we believe there are, as in the formerly contested theories of light, details of less equivocal character adequate to guide if not absolutely to establish our judgment; but the ambiguity of the general aspect is sufficiently shown by the support which such conflicting theories have claimed from it, each in its turn.

Perhaps we are disappointed in our telescope. It will be to no purpose to enlarge our aperture or deepen our eyepieces: we are still confronted by an insoluble mystery. We adopt a fresh mode of investigation, the means of which have been but recently placed in our hands; and we bid the spectroscope exert its analysing power and report to us what is there. And now, under the guidance of Lockyer and Janssen and Huggins, we shall be carried a long way in advance, further than the boldest imagination would have dared to anticipate but a few years back; and we find set before us, as in some strange vision, the unmistakable presence of familiar elements, ninety-three millions of miles away. Yet even this triumph of human ingenuity finds there a boundary that it cannot overpass. The evidence, to a great extent conclusive, is sometimes equivocal, sometimes perplexing: affected probably by influences the force and direction of which we can little estimate. The well-known features often wear a strange aspect, and are associated with incomprehensible surroundings. We have succeeded in interrogating the sun: he has answered us, and his answer will surely be reliable:—

> "Solem quis dicere falsum
> Audeat?"

That is, if we can but comprehend it; but unfortunately the message is not free from obscurity; some of it is in an unknown speech, and "Helium" and "No. 1474" and others of their companions are not only beyond our interpretation, but are likely so to remain. Very wide is the field thus opened for speculation, and very different may be the deductions from the same, or apparently the same, premises, with little possibility of demonstrating that any one combines all the elements of truth. Not one of the current theories has wanted defenders of intelligence and skill; if no one of them clears up all difficulties, no one fails in showing that there is much to be said in its favour; and therefore, as long as no patent absurdity interposes an insuperable bar, we may well exercise toleration to those who do not see through our eyes, or who question to some extent our conclusions. The best result is perhaps not very far in advance of probability, and every claimant has some right to be heard.

Remarks somewhat of this nature may be suggested by the treatise before us, which may be looked upon as an attempt to stem the prevailing current of opinion as to the cause of solar phenomena by showing that they may receive a complete explanation from Zöllner's theory of floating scoriæ, as expanded and developed by the author. The principal results which he has deduced from an extended collation, as it would appear, of the previous observations of others, may be expressed in the following way:—

The sun is to be looked upon as an intensely heated and very gradually cooling ball of monatomic gas, the visible surface of which, or photosphere, is, as Kirchhoff also maintained, composed of iron, with a small admixture of other metals, in a state of glowing fusion, and permeated in every direction by an abundance of incandescent hydrogen, this gas being poured forth abundantly from the exterior of the monatomic nucleus, where the central temperature is sufficiently reduced through decreasing density to admit of the first steps of elemental association. The presence and diffusion of this hydrogen maintains the fused condition of the iron shell, and prevents it from cooling enough to exhibit in every part the

[1] "Die Theorie den Sonnenflecken." Nach den neuesten wissenschaftlichen Forschungen dargestellt von J. E. Broszus. (Berlin, 1884.)

condition which obtains exceptionally in the spots. The "granulated" texture of the photosphere is the result of the eruptive pressure of the internal hydrogen, upheaving and penetrating the glowing mass of iron. The faculæ owe their greater elevation and intensity to an increased activity of the same process; and the chromosphere and the protuberances, whether of the more eruptive or more cloudy character, are traceable to the same origin, the greater brilliancy of the former class being due to the admixture of metallic vapours with the all-pervading hydrogen. The iron shell is not everywhere in a state of equal fluidity, a considerable portion being in a more "pappy" or viscous condition, such as may be seen in our own iron furnaces, which, however, does not render its presence manifest without such a reduction of temperature as to produce opacity. This cooling does not obtain either in the equatorial or polar regions, but is effected in what are known as the "spotted zones," by the overflow of hydrogen from the loftier equatorial strata of the atmosphere. Here, the gas, having been carried up in consequence of the solar rotation into a higher and cooler region, and extending itself laterally as an "equatorial current," descends on the less fluid portions of the photosphere, whence radiation is not so free; they are thus reduced to the more scoriaceous and opaque condition in which they assume the well-known appearance of "spots," while the whirls of cooler vapour on the outside of the main column in its downpour, encountering and tearing away the adjacent metallic edges of the chromosphere, force them to assume the form of those radiated fringes which we know as "penumbræ." The *maxima* and *minima* of the spots, as well as their respective drifting towards the poles or the equator, find their explanation in a "pulsation" or alternate compression and expansion of the globe, chiefly in the direction of its axis, from corresponding alternations in the balance of internal condensation and temperature, each of which is supposed to be in its turn in the ascendant; and though the change of dimension is slight, it is sufficient to give preponderance either to the equatorial or polar current, and, combined with the rotation, to determine the periodicity of the frequency and range of the spots. On the whole, the energy of solar radiation is never compensated; but the waste is so gradual that we have no reason to anticipate any sensible effect for ages to come, and yet so sure that the progressive cooling must terminate in ultimate extinction. In our author's words, "When in some future period of the world the whole of the hydrogen has escaped from the solar nucleus, the sun will cease to shine with its wonted intensity, and will become more and more feeble till at length it hangs in the firmament, a mighty globe of glowing red, as seen from other worlds a ruddy star, which, through rapid cooling, becomes visibly obscured, and, from the formation of everywhere surrounding scoriæ, immersed in deep night,"—a termination of which it may be said that, whatever its intrinsic probability, no reader need look forward to it with the slightest personal apprehension. And were that resplendent body, as Kepler in the exuberance of his imagination believed, the abode of glorious spirits, they might perhaps be supposed to smile at all such anticipations as utterly foreign to the unsearchable designs of the All-wise Creator.

And yet we may not forget that there have been, from time to time, mysterious warnings among the innumerable suns that have their abode in the far depths of space, and we are reminded by no process of argument, but by the evidence of our senses, how untrue it is that "all things continue as they were from the beginning of the creation." The certainty of strange and wonderful catastrophes of outburst or extinction has come to our knowledge, though perhaps only after centuries, or it may have been ages, of the transmission of the recording light: and similar events, to be recognised only by long-distant generations, may be in progress at the present hour. We know very little of the history of the universe, and it becomes us well to speak of such possibilities with caution and reverence. Meanwhile we owe a debt to all who will aid us in the attempt to gratify a very natural curiosity, and to our author among the rest. Some portion of his hypothesis does not come before us for the first time. La Hire in very early days entertained the notion of opaque bodies floating in a fluid mass and occasionally appearing on its surface; and the conclusions of Gautier were very similar as to a partial solidification of metal in fusion; but we must bear in mind that it is only for the diffusion of hydrogen through a liquid envelope of iron that our author claims originality. His ideas are expanded and enforced by so much elaborate reasoning as at any rate to deserve perusal, if they do not succeed in producing conviction. As to this point we may freely confess that the author is more sanguine than ourselves. Some of his arguments are well worthy of attention; but the general character of the treatise is that of an ingenious piece of special pleading, one-sided, but fair and honest in its self-persuasion. A few omissions and mistakes might be pointed out, but they do not impair his argument. The weakness of this, as our readers will have already perceived, lies in the magnitude of some of its assumptions. It might indeed be said that the same objection lies against each of the more commonly received theories; and to this it can only be replied that, though similar in character, it differs in amount; and that the value of any attempt at explanation must be estimated in the inverse ratio of its unproved demands upon our assent.

T. W. WEBB

THE EARTHQUAKE

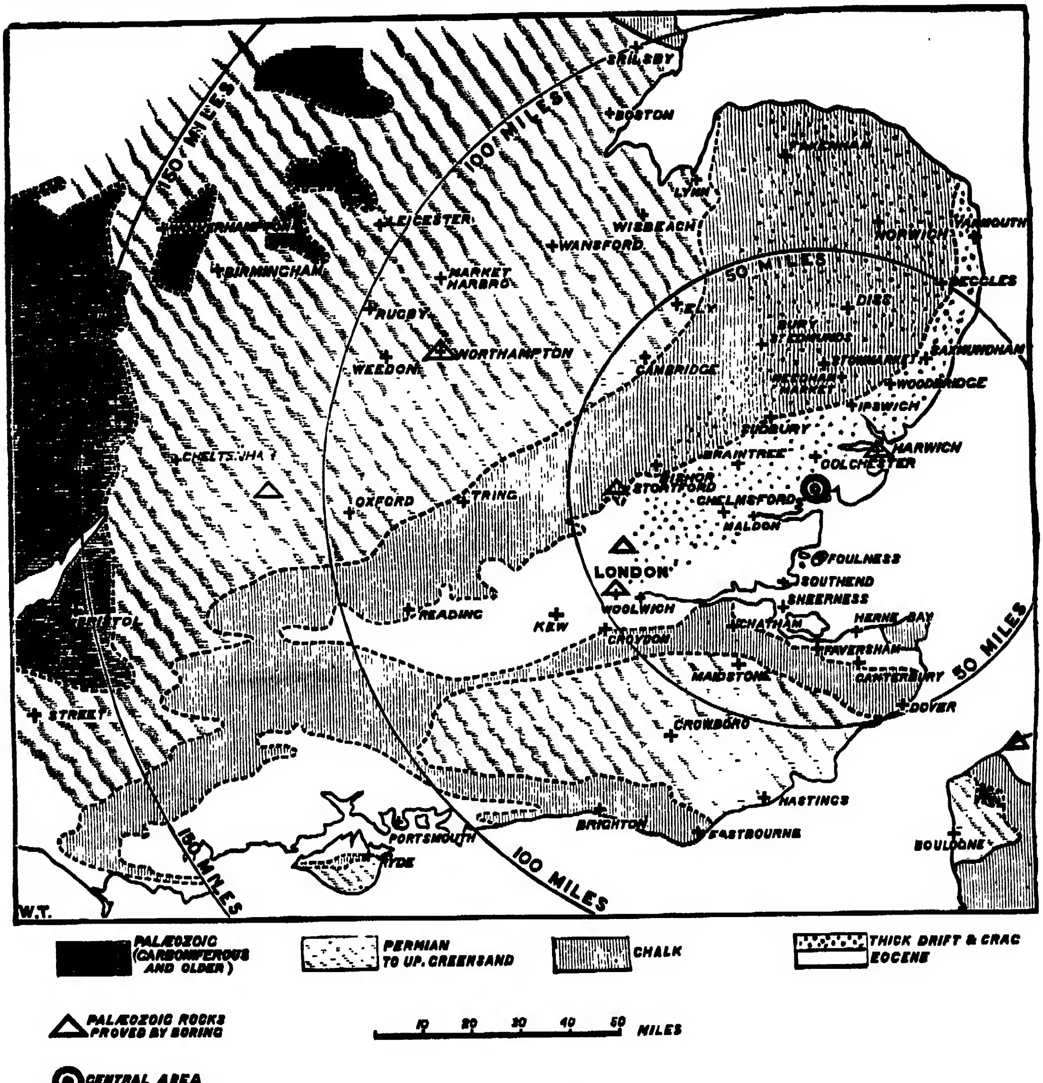
In a previous notice (p. 17) brief mention was made of the more obvious conclusions which follow from a consideration of the observed effects of the earthquake of April 22. Mention was also made of some points upon which further knowledge would be of value, notably as to the result of the earthquake upon wells and springs. Mr. De Rance's letters give important information upon this matter.

The measurements of the water in wells at Colchester and Bocking prove that the level of the water has risen seven feet in the former case and from twenty to thirty inches in the latter case. These facts, and also the curious instance of water spouting from the ground at East Mersea, are quite in accord with what frequently occurs during earthquakes. Mr. Mallet says:—"Fissures containing water often spout it up at the moment of shock. Wells, after the shock, alter their water-level, and sometimes the nature of their contents; springs become altered in the volume of water they deliver. . . . It is important to observe whether any changes of level of water in wells take place *prior* to earthquakes. Statements to this effect have frequently been made, but as yet stand much in need of confirmation."

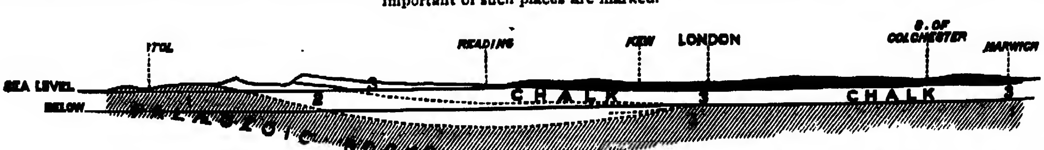
Dr. Taylor's observations that the new and often slightly-built houses have generally suffered less than the old and more solid structures is scarcely what one would have expected. In districts much subject to earthquakes the houses are generally built in such a manner that they yield readily to the vibration, and so mostly escape serious damage. Mr. Mallet indeed believes that if this custom were enforced very little damage would be done. As regards larger and more important structures, the question is not so easily settled; and Messrs. D. and T. Stevenson, in constructing the lighthouses of Japan, employed a peculiar and ingenious contrivance for guarding against the effects of earthquake shocks: this was to interpose a break in the rigid part of the building, and so to prevent the propagation of the shock. Mr. D. Stevenson, in describing this, says:—"The plan I propose for this purpose, which may for brevity be termed an *aseismatic joint*, is

the introduction of spherical balls of bell-metal working in cups of the same material placed between two platforms, the lower cups being fixed to beams forming the foundation, and the upper cups being fixed to the lower beams of the superstructure, thus admitting, within a limited range, free motion of the upper over the lower part of the building." The cost of this was about 90*l.* for each lighthouse.

This plan had some disadvantages: high winds, for instance, gave as much free motion to the upper part as a slight earthquake would do; and there was also consider-



Map of the Earthquake of April 22, 1884. N.B.—The places marked are those at which the shock was felt. In the East of England only the more important of such places are marked.



Section from Bristol to Harwich, showing the probable range of the Palæozoic Rocks. 1, Palæozoic Rocks (Carboniferous and Older); 2, Permian to Upper Greensand; 3. Chalk.

able movement of the lights during cleaning. The lighthouse-keepers, therefore, screwed up the metal plates, so that when an earthquake came sufficiently powerful to test the value of the plan, the structure was rigid and the glasses were broken. This plan was afterwards abandoned, and Mr. R. H. Brunton adopted the plan of constructing the lighthouses with "great weight and solidity, thereby adding to their inertia and checking the oscillation." Mr. W. Lloyd, from his experience in South America, believes that the more solid the structures the better they resist earthquake shocks. Mr. Woods, on the other hand, found that in Peru lightly-built structures of

iron were unharmed by earthquake shocks which did enormous damage to other buildings. This apparent contradiction may perhaps be explained by supposing that a lightly-built structure would give to every movement, and a very massively-built structure would resist such movement; either would bear a considerable earthquake shock unharmed, but buildings of intermediate resisting power would be destroyed.

Upon the twisting motion often noticed in earthquakes, and especially referred to by Dr. Taylor as observed at Langenhoe, Peldon, Fingrinhoe, and Abberton, much difference of opinion has existed. From the time of Aristotle it has been commonly attributed to a vorticose movement of the earth's surface at the part affected. The effects produced seem at first quite to accord with this explanation, as when in Japan a chimney ten feet high, and two feet by three, is broken in two, the upper half being twisted diagonally round without other fracture or displacement; or when, at Mendoza, a church tower has its lower story uninjured, its middle story turned through an angle of nearly 90°, and its highest story thrown completely over. But Mr. Mallet, who recorded similar cases in the Neapolitan earthquake of 1857, denied that this is in any case the correct explanation, and he believed that the twisting is best explained by resolved motions, due to the transit rectilinearly of the shock.

As regards the range of the recent earthquake very little more is known than was recorded during the first few days after the shock. The most important new fact is that mentioned by Dr. Prince of the shock being observed at Crowborough in Sussex; this proves that the Wealden area was affected, although the shock must have been very slight. Probably if the Palæozoic rocks were as near the surface there as was once hoped the shock would have been more distinctly felt.

There can now be little doubt that the origin of the shock was vertically under West Mersea or thereabouts, and that the wave must have travelled in all directions away from that area, but not necessarily with equal force and rapidity in all directions. The observations as to the direction of motion generally agree with this view; but in the neighbourhood of London there are some curious differences. The observations in London itself generally give an east and west direction, whereas some on the north side of London appear to point to a more north and south direction.

No observations are recorded of the connection of the earthquake wave with minor details of geological structure, such as the outcropping of certain hard or soft beds, or with lines of fault. The only instance of the latter kind known to me is at St. John's, near Greenwich, where the shock was felt very close to a fault, well exposed in the railway cutting just west of St. John's Station. But another and perhaps better explanation is that the shock was there felt by an invalid lying quietly in bed, and very sensitive to movement.

In the map here given, an attempt has been made to mark the positions of all places at which the shock was felt, so far as can be learnt from published accounts; but in Essex, Suffolk, and North Kent only a few of such places could be marked. By marking the outcrops of the older rocks (Carboniferous and earlier), the possible connection of these with the travel of the earthquake wave may be seen. This is made clearer by the section. The position of the Palæozoic rocks is known at Harwich and London; there is some uncertainty as to their position under Reading and Colchester, but for the purpose intended, and regard being had to the depth at which the shock must have originated (certainly far within the Palæozoic rocks), the line drawn is sufficiently near the truth. We can see how the shock can have been propagated through the hard Palæozoic rocks and been felt where these are bare or thinly covered with newer rocks, whereas through the thick and softer Secondary and Tertiary rocks the wave might travel a shorter distance. Possibly also this section may suggest an explanation of the double shock which was sometimes recorded: the first would be that travelling quickly through the hard Palæozoic rocks, the second that propagated more slowly through the softer overlying newer rocks.

W. TOPLEY

VOLCANOES ON THE SHORES OF LAKE NYASSA, AFRICA

DR. LAWS, on his return to Europe from the mission station at the north end of Lake Nyassa, passed by Naples, where I had the pleasure of meeting him. Amongst other information that I gleaned was that pumice-stone is very abundant in the locality above-mentioned and on the shores of the lake, where pebbles of coal are also met with. He also informed me that many of the rocks had a striking resemblance to the volcanic tufas around Naples. Dr. Laws happened to have a specimen of pumice, which he kindly placed at my disposal.

The specimen forms about two-thirds of a flattened ellipsoidal pebble of about $1\frac{1}{2} \times 1\frac{1}{4} \times \frac{3}{4}$ inches in diameter. It is of a dirty buff colour, darker in spots, the result of oil stains in packing. The grain is fine; there are very few large cavities, which are multilocular, with smooth-walled spheroidal-shaped alveoli. The specific gravity of the mass is light. The characters indicate great homogeneity of material, only a moderate amount of dissolved water in the original magma, and an eruption of true paroxysmal type. A few minute crystals of sanadin are discernible with the naked eye, and rarely also a small black spot, which we shall see to be pyroxene.

It is easily sectionised, and when examined under a low power, shows a remarkable uniformity of size in the pores. Those near and opening upon the surface contain a few diatoms indicating the action of water as the cause of the pebble-like form.

The magma is a perfect glass of light straw-colour. Scattered through it are a few small irregular crystals of sanadin, fairly clear, but of irregular boundaries in many cases, as if they had wavered between crystallisation and fusion. A few are twinned on the Carlsbad type, and a few also present fine wavy striation parallel to their longer axis. At one spot were two or three sanadin crystals inclosing dark brownish-green pleochroic microliths, too irregular to measure the angle of extinction, but which looked very much like amphibole. There were to be seen a few well-formed crystals of pyroxene of light pea-green colour, quite free from pleochroism, and with characteristic crystalline boundaries and cleavage, with absence of inclosures. In the immediate neighbourhood of the large pyroxene crystals were a few microliths of the same mineral; the average angle of extinction was 49°, and ranging within narrow limits. No other "formed" materials were discernible except a mass of dirty brown, dusty matter involved in a group of sanadin crystals, which might be magnetite. The whole character of the specimen is strikingly like some of the basic pumices of Monte Somma, and almost indistinguishable from some specimens of Phase VI. Period I (*Quart. Journ. Geol. Soc.*, January 1884).

I regret that for want of a balance I have not been able to analyse the specimen, though I am inclined to place it amongst volcanic rocks containing less than 55 per cent. of silica.

The specimen itself is in no way remarkable, but it is interesting as indicating the existence of continental volcanoes some hundreds of miles from the seashore, although in the immediate neighbourhood of a great lake, as also an additional grain of acquaintance with the geology of the mysterious interior of the "dark continent."

My informant has promised to forward me a collec-

tion of rocks on his return to Lake Nyassa, which will give us a more detailed knowledge of that interesting volcanic and also coal-bearing region.

Naples, April 26 H. J. JOHNSTON-LAVIS

NOTES

Two eminent chemists died on Monday, both born in the same year—1817—M. Karl Adolph Wurtz and Dr. R. Angus Smith, F.R.S. M. Wurtz, who was a pall-bearer at the funeral of Dumas, is stated to have died from the bursting of a blood-vessel; he was a candidate for the vacant post of Perpetual Secretary to the Academy of Sciences. Dr. Angus Smith had been in failing health for some time. A detailed account of the careers of both chemists we must postpone till next week.

THE Council of the Royal Geographical Society have selected the following travellers for honours:—Mr. A. R. Colquhoun, for his travels in China, and Dr. Julius von Haast, for his systematic exploration of the southern island of New Zealand, the Royal Medals; Mr. W. W. M'Nair, the Murchison Grant; Mr. Emil Boss, the Bach Grant; Mr. W. O. M'Ewan, the Cuthbert Peek Grant; and Dr. Haast, Dr. Max Buchner, and M. Ferdinand de Lesseps as honorary corresponding members.

GERMANY has been prompt in acknowledging the services of its Cholera Commission; by acclamation a bill was passed by Parliament on Tuesday awarding a sum of 135,000 marks to Dr. Koch and his companions.

THE Council of the British Association have resolved not to entertain any more applications for membership prior to the Montreal meeting, when members and associates will be elected as at any other meeting. The number of tickets applied for is 722.

DURING the discussion in the Dominion House of Commons upon the vote of 25,000 dollars to defray the expenses of the meeting in Montreal in August next of the British Association, some further arrangements for the reception of members were made known. The excursion to the Rocky Mountains will, it is announced, take place on September 4, the members being taken by the New Canadian Pacific Lake route, where specially-constructed steamers make direct connection with the railway on each side. The excursion will probably occupy two weeks, and arrangements have been made that members of the party may not be put to greater expense than one dollar and a half per diem during the trip. Of the 25,000 dollars granted by the Dominion Parliament, 5000 will be used to defray the expenses of the meeting itself, and a fund is being raised to guarantee the Association against loss in connection with the publication of their proceedings. In addition to the Rocky Mountains excursion, excursions will be arranged to Ottawa, Quebec, and probably to Belœil Mountain, a locality of great geological interest. Active preparations are being made at Montreal, Toronto, and other places which will be visited, to give the members a due reception. It has also been arranged by the Associated Atlantic Cable Company that social cable messages to and from the delegates and their friends shall be sent free of charge. This is regarded as a considerable contribution towards the success of the meeting in Montreal.

THE French Association for the Advancement of Science meets at Blois this year from September 4 to 11.

PROF. HUXLEY was examined on Tuesday before the Select Committee of the House of Commons on the Education, Science, and Art Departments. He stated that in his opinion greater attention should be paid in our public schools to physical science. The Endowed Schools Commission was appointed to a great extent on account of the general state of apathy which existed in connection with the endowed schools. There is a distinct provision that a certain proportion of marks should be given to science and modern languages. The system, however, is not well carried out in the public schools; not more than two hours a week are given to science. There is no doubt, Prof. Huxley stated, that the Oxford and Cambridge School Examination Board Regulations tend to handicap science extremely. The examiners found their examinations on what is taught in the schools, and the schools found their instruction on the requirements of the examiners. He regarded the present system of education as wrong from top to bottom. The subjects on which most stress is laid are really luxuries, while those which are regarded as luxuries are really the most essential. The present system of education in the country shuts out young men from many employments for which they should be eligible, and tends to the employment of foreigners. Prof. Huxley thought that an influential Minister, with a seat in the Cabinet, might do a great deal to improve education. It would be his business to judge in what direction the educational system was tending, and to enforce on the educational bodies a modification of their system in the desired direction. He would give the Minister power to insist upon more time being given to science and modern languages.

THE Royal Society *conversazione* on the 7th inst. was well attended, and the exhibits, mainly connected with physical science, interesting. Mr. J. Wimshurst exhibited the continuous electrophorus. This instrument consists of two glass disks, revolving in opposite directions upon the same axis. To the outer faces of the disks radial metallic sectors are attached, which in their turn are touched by brushes of fine wire. It is self-exciting under almost any condition of atmosphere, parts freely with its electricity, and the current will not change its direction while the instrument is at work. In Room II. was shown a map of the earthquake in Essex (April 22, 1884), with photographs of damaged buildings. In Room III. Messrs. Elliott Brothers showed some electrical and magnetic apparatus, including a simplex repeater board, Wheatstone's transmitter, Wheatstone's perforator (new form), portable electric lamps, worked by Skrivanow batteries, the Kew Committee magnetometer, and a selection of electrical and other instruments. In the principal library was a compound magnet, with bifilar suspension, showing the change in total moment produced by dividing a magnet into short lengths, exhibited by Mr. R. H. M. Bosanquet. The magnet consists of eighteen pieces of hard steel which, fitted end to end, form a cylindrical bar. These can be placed in the suspension tray either as a bar, or dispersed as separate pieces. When placed together as a bar the moment is between seven and eight times as great as when the pieces are separated. The equilibrium position of the suspended tray is east and west. When a magnet is placed in the tray a deflection takes place towards north and south. The tangent of this deflection measures the moment, according to the ordinary principles of bifilar suspension. Mr. Hilger exhibited various spectroscopes and a 6½-inch achromatic object glass in a mount of new construction. A new photometer and Dworak's sound radiometer, were sent by Mr. Preece; and Hughes' magnetic balance, and Prof. Minchin's absolute sine electrometer, by Mr. Groves. An interesting apparatus for the generation and distribution of ozonised air, to be placed in the Hôtel-Kursaal de la Maloja, Upper Engadine, was exhibited by Dr. A. Tucker Wise. To render the air as pure as possible in this building, ozone is added to the internal atmosphere in connection with the general plan of ventilation. By means of valves this ozonised air can be turned into any room at the rate of from 60 to 100 cubic metres per hour for each occupant. The Rev. S. J. Perry exhibited a selection from the series of drawings of the solar surface made at the Stonyhurst Observatory from 1880 to 1884.

AT the next meeting of the Society of Telegraph Engineers and Electricians, to be held on Thursday, May 22, at the Institu-

tion of Civil Engineers, Mr. W. H. Preece, F.R.S., will give a review of the work done by the Electrical Congresses of Paris, and will describe the new units determined upon.

THE Lord Lieutenant of Ireland has appointed the following Commissioners to inquire into the management of the Queen's Colleges and Royal University in Ireland :—R. P. Carton, Q.C., Mr. George Johnstone Stoney, F.R.S., Rev. Dr. Gerald Molloy, Rector of the Catholic University, Mr. Wm. Jack of Glasgow University, and Surgeon-General Marsten. Mr. N. D. Murphy, barrister, is appointed secretary.

THE Engineering Department of the Yorkshire College at Leeds is about to be considerably enlarged, to admit of more students at the classes, and towards this object Sir Andrew Fairbairn, M.P., and Sir John Hawkshaw have each contributed 1000*l*.

THE steamer *Alert*, one of the vessels to be engaged in the Greely Relief Expedition, sailed from New York on May 10.

THE eminent Swedish astronomer, Prof. H. Gyldén, at present chief of the Stockholm Observatory, has been called to the Professorship of Practical Astronomy at Göttingen.

HERR AUGUSTIN GAMÉL of Copenhagen has offered to despatch the *Dijmphna*, under Lieut. Hovgaard, to Franz-Josef Land in the summer of 1885, provided the Danish Government will contribute part of the expenses. No contribution will be accepted from foreign nations.

PROF. NORDENSKJÖLD has executed a detailed map of that part of the east coast of Greenland which he visited last summer, situated beyond Cape Dan, known from Lieut. Graah's journey. The peninsula on which the cape is situated he has named "King Christian's Island," and the harbour in which he landed "King Oscar's Harbour." Several other points have been named after celebrated Swedes and Danes.

THE Finnish Senate has petitioned the Czar that all members of the forthcoming hydrographical expedition in the Baltic, which will cost about 100,000 marks, shall be Finnish subjects, as so little progress with such labours seems to be made under Russian naval officers.

THE St. Petersburg Horticultural Exhibition and Botanical Congress, which was deferred last year owing to the coronation of the Czar, was opened on May 5. Mr. H. J. Elwes, F.L.S., of Preston House, Cirencester, was requested by the Science and Art Department to attend as the delegate on behalf of this country, and has been accredited.

MR. J. E. MARR, M.A., Fellow of St. John's College, Cambridge, has been appointed by the Council to lecture in geology.

A VIOLENT shock of earthquake, having an undulatory character, was felt at Spoleto at 8 o'clock on Friday night. The bells were set ringing and the clocks stopped. On Saturday, at 9.50, a slight shock in the direction of from north-west to south-east was felt at Cosenza, and at Paola a somewhat stronger shock was felt.

THE additions to the Zoological Society's Gardens during the past week include a Barbary Ape (*Macacus inuus* ♀) from North Africa, presented by the Countess of Craven; a Moufflon (*Ovis musimon* ♂) from Sardinia, presented by Col. Knox and the Officers of the 1st Battalion Scots Guards; a Common Raccoon (*Procyon lotor*, white variety) from North America, presented by Mr. F. J. Thompson; a Ground Hornbill (*Buceros abyssinicus*) from West Africa, presented by Capt. Rupert La T. Lonsdale; a Gold Pheasant (*Thaumalea picta* ♀) from China, presented by Mr. Frank Reed; two Peregrine Falcons (*Falco peregrinus*), European, presented by Lieut.-Col. Drummond Moray; two Alligators (*Alligator mississippiensis*) from the Mississippi, presented by Mrs. Andrade; a Green Tree Frog (*Hyla arborea*), European, presented by Mr. G. W. Obicini, F.Z.S.; twenty-one River Lampreys (*Petromyzon fluviatilis*) from British rivers, presented by Mr. T. E. Gunn; two Japanese Greenfinches (*Ligurinus sinicus* ♂ ♀) from Japan, two Common Crowned Pigeons (*Goura coronata*) from New Guinea, purchased; a Canadian Porcupine (*Erithizon dorsatus*), five Long-fronted Gerbilles (*Gerbillus longifrons*), two Variegated Sheldrakes (*Tadorna variegata*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

THE APPROACHING RETURN OF OLBERS' COMET.—Now that the comet of Pons is drawing away from us, attention may be directed to another comet belonging to the same group as regards length of revolution, viz. that discovered by Olbers at Bremen on March 6, 1815, and last observed by Gauss at Göttingen on August 25. While it was still under observation an elliptic orbit was assigned by several astronomers, including Bessel and Gauss, who found the period between seventy and eighty years. Bessel subsequently discussed all the observations available to him, in a memoir published in the *Transactions of the Berlin Academy*, and, after determining the most probable orbit in 1815, he calculated the planetary perturbations to the time of ensuing return to perihelion, which he fixed to 1887, February 9, the effect of the perturbations being to accelerate the return by about 825 days.

An elaborate investigation of the elements of Olbers' comet and the effects of planetary attraction during the current revolution has been lately made by Herr F. K. Ginzel, of Vienna: it gained the prize of the Haarlem Society of Sciences, and was published by the Society in 1881. The author has availed himself of the improved values of the planetary masses and the other advantages which the astronomy of the last seventy years has placed in our hands, and has produced an interesting and skilfully-worked discussion of the motion of the comet since it passed out of view in 1815. He commences with a solar ephemeris, and coordinates X, Y, Z, founded upon Leverrier's Tables, and extending from March 4 to August 27, followed by an ephemeris from Bessel's ellipse of the comet's geocentric right ascension and declination and log. distance for the same period. In the next section the observations are as far as possible newly reduced, great care and trouble having been bestowed on the determination of the places of the comparison stars from the most reliable catalogues. It may be mentioned that there are observations at fourteen observatories, including Greenwich, where the comet was followed from May 22 to July 7; the series newly reduced are those of Berlin, Göttingen, Königsberg, Paris, Prague, and Seeberg. The necessary data for reduction of mean to apparent places of the comparison stars follow. The effect of parallax is applied to the comet's observed positions, and we have then the entire collection of deduced geocentric places, with the Berlin mean times of the observations.

In Bessel's investigation 187 observations were utilised; Ginzel has the greatly increased number of 346. The perturbations of Mercury, Venus, the Earth, Mars, Jupiter, Saturn, Uranus, and Neptune are next calculated for the period over which the observations extend; twelve normal positions are formed, and cleared of the effect of planetary attraction; then, in the usual manner, Bessel's elements are corrected by equations of condition, and the following definitive orbit for 1815 is obtained:—

Perihelion passage, 1815 April 26·030146 Berlin M.T.

Longitude of perihelion	149° 2′ 2″·8	M.Eq. 1815·0
,, ascending node	83 28 46·7	
Inclination...	44 29 50·8	
Eccentricity	0·93114958	
Log. perihelion distance	0·0837998	

Hence there results a revolution of nearly 74 years. The limits of uncertainty in this period are then examined, and found to be 75·68 and 72·33 years, and thus Ginzel concludes that the time of revolution given by the complete discussion of the observations of 1815 is in doubt to the extent of 1·6 year, or about a year and seven months.

In the next section of the memoir are presented the details of the laborious work involved in the calculation of the effect of planetary attraction during the actual revolution. The separate effect of each of the planets Jupiter, Saturn, Uranus, and Neptune

is assigned, and as regards the period, will be found from Ginzel's numbers to be—

	days
For Jupiter	−799·16
Saturn	− 27·27
Uranus	− 7·53
Neptune	− 2·76

These figures show a total acceleration of 836·72 days, and hence the most probable epoch of the next perihelion passage is found to be 1886 December 16·9 G.M.T.

After remarks upon the physical observations made in 1815, and Bessel's observation of a nearly central occultation of a star by the comet on April 26, we have extensive sweeping ephemerides to facilitate the rediscovery at the approaching return; the places are given for every tenth degree of the sun's longitude, and of the true anomaly from − 120° to +120°. In view of the uncertainty in the length of the comet's period, it may be well to commence the search in 1885.

In a supplement Ginzel examines the effect of the attraction of the smaller planets Mercury, Venus, the Earth, and Mars from March 1815 to February 1817; also the possible effect of a resisting medium: these are found to be too small to be worthy of consideration practically.

The elements assigned by Ginzel's investigation for the comet's next appearance are:—

Perihelion passage, 1886 December 16·9338 Berlin M.T.

To which corresponds a period of revolution of 71·843 years.

THE BUILDING OF THE ALPS[1]

II.

I PASS now to the section of the Simplon. On the southern side, deep in the glen of the Doveria, in the vicinity of the gorge of Gondo, we find a mass of granitoid gneiss, which recalls to mind that already described from the wildest portion of the upper valley of the Reuss. We may, I think, with confidence affirm that, whatever be the true nature of this rock, we are again touching the foundation-stones of the rock masses of the Alps. As we approach Algaby, the granitoid gneiss becomes more distinctly bedded and variable, a thin band of micaceous crystalline limestone is passed, and presently the more rapid ascent of the pass begins. Hence to beyond the summit we traverse, so far as can be seen, a great series of bedded gneisses, often coarse and even porphyritic, and of schists. The same are displayed in the crags of Monte Leone on the east and of the Rossbodenhorn on the west. As shown in Prof. Renevier's valuable section, bands of crystalline dolomitic limestone, and of hornblendic and garnetiferous schists occur in various places on either side of the Simplon road. Then, after descending about half way to Brieg, we strike the group of the Lustrous Schists, with the usual calcareous zone in the lower part. Prof. Renevier does not attempt to unravel the complexities of the strata which compose this portion of the central ridge of the Alps, and I feel that my slighter knowledge makes caution yet more imperative; but I think we are justified in asserting that we have evidence of an upward succession from the coarse granitoid fundamental gneisses, through more variable and bedded gneisses, to a group which recalls the garnetiferous schists, so finely developed on the southern flanks of the St. Gothard—a group also traceable in the upper portion of the Binnenthal, though apparently far less perfectly developed. I think also that in the gigantic anticlinal of the Simplon we have evidence of sharp flexures on a great scale; and that these garnetiferous schists are only here and there preserved as the lower ends of infolded loops, so that the bulk of the *massif*, and, so far as I can tell, the actual summit ridges of the Rossbodenhörner and Monte Leone, are composed of the bedded gneisses and strong schists, and perhaps of the more friable gneisses which have been already described in the mountains further to the east.

The mountains further west—the aspiring peaks which rise around the two branches of the Visp, including among them some of the highest summits of the Alps, such as Monte Rosa, the Mischabelhörner, the Matterhorn, and the Weisshorn—offer indeed magnificent sections, but are full of difficulty. The fundamental gneiss, if I mistake not, is occasionally exposed—as, for example, in the rocks of Auf der Platte, at the base of Monte Rosa; and in parts of the Mischabelhörner blocks of coarse granitoid rock, often very porphyritic, which I refer to the same series, are brought down by the glaciers. There are also mica schists in plenty, such as the summit rocks of Monte Rosa and the backbone—if the phrase be permitted—of the Mischabel- and Saaser hörner, which I refer to the second zone already described—that of the bedded gneisses and strong mica schists. I have also seen specimens which closely resemble the garnetiferous schists of the St. Gothard district, but we meet in this district with a group of rocks which, if not altogether unknown before, appear now to be developed to an exceptional extent, and to become an important factor in the Alpine crystalline series.

Those who are familiar with the environs of Saas and Zermatt will remember how frequently schists or schistose rocks of a greenish colour occur. Sometimes they are interbedded with strong mica schists, or schisty quartzites, sometimes they form homogeneous masses of considerable extent. It is possible that some of the latter are intrusive masses of serpentine, to which subsequent pressure has given a schistose aspect; certainly there are occasional masses of coarse gabbro, which I think undoubtedly an intrusive igneous rock; but still, making all allowance for such cases, there is in this region a considerable mass of greenish hornblendic, talcose, and serpentinous rocks which appears to be non-igneous in origin. We find these all around Zermatt. They form the ridges of the Gorner Grat and of the Hornli. They break out through the snows of the Breithorn and Little Mont Cervin, and constitute no inconsiderable portion of the mighty obelisk of the Matterhorn. The whole of that peak, according to the investigations of Sgr. Giordano—and with this my own recollections correspond—consists of an apparently regularly bedded series of serpentinous and micaceous schists, and of greenish gneisses, with the exception of a gabbro, developed on the western side, which I have no doubt is an intrusive rock. Can we trust these indications? Are we justified in assigning to this zone, with those characteristics, a vertical thickness of more than a mile? To these questions I can give at present no answer, further than to state that I am convinced that, notwithstanding the apparent regularity of the bedding in this and the neighbouring peaks, there are really great folds which patient scrutiny may at length unravel, and that this zone of greenish rocks—for which Alpine geologists have proposed the name of *Pietra Verde* group, appears to underlie the garnetiferous series of silvery mica schists, and either to overlie or replace the upper portions of the banded gneiss series which succeeds to the fundamental series.

I do not propose to weary you further with the details of Alpine sections, except that I must add a few words upon the extent of this remarkable series to which I have now introduced you. On the northern side of the watershed in the Swiss Alps, so far as I am aware, it is not generally strongly developed, except in certain localities in the southernmost of the three ranges which make up the whole chain, but in parts of the Tyrol it is well displayed. It borders—the mica schists sometimes dominating—the fundamental gneiss in the Oetzthal *massif;* it forms the peak of the Gross Glockner; it meets us on the Brenner Pass and elsewhere overlain by and folded up with rocks which, if my memory do not mislead me, are the equivalents of the Lustrous Schists of more western districts.

Again, it is finely developed, seemingly in succession to bedded coarser gneiss, in some of the peaks of the Bernina range, and it occupies a considerable tract about the heads of the valleys to the south. It may be traced, indeed, over a great zone, and with but slight interruption all along the southern slopes of the Alps, even to the south of the head waters of the Po, forming many of the grandest peaks in the Graian, Tarentaise, Maurienne, and Cottian Alps; and we find traces of it overlying the coarse granitoid series in the *massif* of the Alps of Dauphiné.

Sections, indeed, in the neighbourhood of Biella, according to Gastaldi and Sterry Hunt, exhibit the Pietra Verde group overlying the upper or more bedded portion of the great gneissic or basal series, and succeeded by the group of friable gneisses, described above as closely associated with the garnetiferous schists, in a manner that suggests an unconformity. Under ordinary circumstances we should not hesitate to admit

[1] Lecture by Prof. T. G. Bonney, D.Sc., F.R.S., Pres. G.S., at the Royal Institution, April 4. Continued from p. 46.

that there is considerable evidence in favour of this break, and some for one between the Pietra Verde group and the stronger gneisses and schists below; but in mountain regions we fear to trust our eyes. The evidence, however, in certain districts in favour of a break at the base of the Lustrous Schists is yet stronger. If I am right in regarding the Lustrous Schists as forming one group with the older part of the Bundnerschiefer of the Grisons region, and of the Thonschiefer of Von Hauer in the Eastern Alps, a study of the geological map will show that it is difficult to explain the relation of these beds to the underlying gneisses and schists without such an hypothesis. What I have myself seen in regard to the Lustrous Schists is strongly in favour of a great break in some localities. On the south side of the St. Gothard we have in the Val Piora the Lustrous Schists apparently in true succession with the representatives of the garnetiferous group of the Val Tremola, yet on the northern side, in the Urserenthal, the latter series is wanting, and the gneisses which underlie it appear to be immediately succeeded by the Lustrous Schists. This, however, might be explained by a complication of faulting and folding. What I have seen in the Binnenthal is harder to explain. At the head of the Hohsand Glacier, just below the peak of the Ofenhorn, we have a coarse but bedded gneiss, which I should correlate with the series immediately overlying the granitoid gneiss so often mentioned as the lowest rock of all. Glancing towards the north, across the snowfield, we see this rock in the base of the Strahlgrat distinctly overlain by the Lustrous series, with its characteristic band of limestone or dolomite. This series swoops down for some 2000 feet, and we cross it in the upper basin of the valley below, while yet further down the valley I detected the characteristic garnetiferous schist, of which, however, there is no great development. If this be the result of faulting and folding only, it is certainly very remarkable.

But I must linger no longer over details. The passing time warns me that I must attempt briefly to describe the general process of the building of this great mountain group of Europe. I have, I hope, proved that the metamorphic rocks of the Alps, if we may trust mineral similarity and mineral and lithological sequence, are vastly older than the Carboniferous period, and that in this ancient series a certain succession may be made out. If we may reason from the analogy of other regions, we may assign to the whole of their latest group (the Lustrous Schists) an antiquity greater than the earliest rocks in which indisputable traces of organic life have been found. One point, however, I should notice before proceeding further. It might perhaps be said—it has indeed been said—that the crystalline schists and gneisses of the Alps are the result of the great earth movements by which the mountains were upraised, when heat and pressure changed mud into schists and felspathic sandstone into gneiss. I have shown you that we can trace a mineral succession in the crystalline series of the Alpine chain, and that some at least of these are earlier than the Carboniferous period; but I can add to the proofs that these great rock masses had assumed in the main their present mineral structure when these movements occurred. We meet with some rock masses whose structure is doubtless due to the pressure which they have undergone. This is the case with all cleaved rocks, as was lucidly explained twenty-eight years since by Prof. Tyndall in this very room. We meet also with schists, where, from the arrangement of the mineral constituents, we have good reason for supposing that they were developed when the rock mass was exposed to a pressure definite in direction. Here the lines of different minerals, which we believe indicative of an original structure in the rock, are often wrinkled; the more flaky minerals commonly lie with their broader planes parallel, but, notwithstanding this, there is no very definite cleavage in the rock mass, nor tendency to separate easily along the different mineral layers. Specimens of such rocks may be obtained in the Alps, but there are others in which the layers have evidently been crumpled up after the period of mineral change: the bands of quartz and felspar have been, as it were, crushed together, the flakes of mica are sometimes crumbled and sometimes twisted round into new positions.

The subject is a technical one, so I must ask you to accept my statement, without the long details of microscopic work on which it is founded, that the older Alpine rocks frequently testify to having undergone an extraordinary amount of crushing. In the middle of coarse gneisses, for example, streaks and thin bands of a mica schist may be found, which are not due to an original difference of materials, but to the fact that here and there the original rock has yielded to enormous pressure, and has been crushed *in situ* into lenticular bands of rock dust, from which some new mineral developments have taken place. You may notice also in some regions, where you would classify the rocks at first sight as mica schists, that a close examination of the broken surfaces at right angles to what appear to be planes of foliation reveals a structure resembling a coarsish gneiss. The microscope shows that the rock is really a gneiss, somewhat crushed, and that the micaceous layers are of extreme tenuity—mere films, which do not seem to have been original constituents. The gneissic mass has been crushed, cleaved, and on the cleavage planes films of a hydro-mica have been developed. We cannot fail to be struck, when once our eyes have been opened to it, by the frequency of a slabby structure in the more central parts of the Alpine ranges, the surfaces of these slabs being coated with minute scales or films of mica. These are really records of a rude cleavage which has been impressed upon the more central and less flexible portions of the Alps during the great earth movements which they have undergone since they were first metamorphosed.

Thus in the building of the Alps our thoughts are carried very far back in the earth's history, far beyond the earliest strata of the Palæozoic age. Under what conditions were these great homogeneous granitoid masses of the fundamental gneisses formed? They differ on the one hand from granites, on the other from the ordinary gneisses; from the former their differences are but slight, and of uncertain value, yet into the latter they appear to graduate. There is nothing like to them in any subsequent rock group, and, so far as our knowledge at present goes, they appear to be the records of a period unique in the world's history. This may well be. When the dry land first appeared, when the surface of the earth's crust had not long ceased to glow, when the bulk of the ocean yet floated as a vapour in the heated atmosphere, when many gases now combined were free, we can well imagine that the earliest sediments would be deposited under conditions which have never been reproduced. In the later schists, with their more frequent mineral changes, their distinct stratification, and their beds of quartzite and of limestone, we may mark the gradual approach to a more normal condition of things. Some, such as the Lustrous Schists, may indeed be contemporaneous with our earliest Palæozoic rocks; but I confess that to myself the evidence appears more favourable to the idea that all are more ancient than the period which we call Cambrian, and that the majority are so I feel little doubt.

Supposing, then, that I am right in considering all the Alpine schists, even the Lustrous group, to be pre-Cambrian, we have a vast interval of time which has left no record in those districts of the Alps of which I have been speaking. It is not till we come to the Carboniferous period that we can identify any pages in the life-history of the earth. We are justified with regard to these in the following conclusions:—

That in the place of the Alps there was at that time an upland district, composed of gneisses and schists, in substantially the same mineral condition as they are at present, together with slaty beds in a comparatively unaltered condition, which district was fringed by a lowland covered by a luxuriant vegetation. Prior to this time, also, the metamorphic rocks of the Alps had been so far folded and denuded that the coarser gneisses were in many places laid bare, and contributed the materials which we now find in such beds as the Val Orsine pudding-stone. Whether there was a pre-Triassic mountain chain occupying some parts of the present Alpine region we cannot venture to say, but I think we may unhesitatingly affirm that there were pre-Triassic highlands.

After the close of the Carboniferous period, and anterior to the middle part of the Trias, there were volcanic outbursts on a large scale in more than one region of the Alps—notably in the district near and to the east of Botzen. After this commenced a period of subsidence and of continuous deposition of sediment. This seems to have begun earlier and to have been at first more rapid in the eastern than in the western area. Since in the former the Triassic beds are generally much thicker and more calcareous than in the latter, one is tempted to imagine that the eastern area quickly became a coraliferous sea, with an occasional atoll or volcanic island. Henceforward to the later part of the Eocene the record is generally one of subsidence and of deposit of sediment. Pebble beds are rare: the strata are grits, shales (or slates), and limestones. Whence the inorganic constituents of these were derived I cannot at present venture to suggest, but though conglomerates are rare, there are occasional indications that land was not very distant. In the eastern Alps, however,

the position of some of the Cretaceous deposits and the marked mineral differences between these and the Jurassic seem to indicate disturbances during some part of the Neocomian, but I am not aware of any marked trace of these over the central and western areas. The mountain-making of the existing Alps dates from the later part of the Eocene. Beds of about the age of our Bracklesham series now cap such summits as the Diablerets, or help to form the mountain masses near the Tödi, rising in the Bifertenstock to a height of 11,300 feet above the sea. Still there are signs that the sea was then shallowing and the epoch of earth movements commencing. The Eocene deposits of Switzerland include terrestrial and fluviatile as well as marine remains. Beds of conglomerate occur, and even erratics of a granite from an unknown locality, of such a size as to suggest the aid of ice for their transport. For the present I prefer, for sake of simplicity, to speak of the upraising of the Alps as though it were the result of a few acts of compression, though I am by no means sure that this is the case. Thus speaking we find that in Miocene times a great mountain chain existed which covered nearly the same ground as the present Alpine region of Mesozoic and crystalline rocks. To the north, and probably to the south, lay shallow seas, between which and the gates of the hills was a level tract traversed by rivers, perhaps in part occupied by lakes. Over this zone, as it slowly subsided—in correspondence, probably, with the uplifting of the mountain land—were deposited the pebble beds of the nagelflue and the sandstones of the molasse.

Then came another contraction of the earth's crust; the solid mountain core was no doubt compressed, uplifted, and thrust over newer beds, but the region of the softer border land, at any rate on the north, was apparently more affected, and the sub alpine district of Switzerland was the result. I may here call your attention to the fact that, whether as a consequence of this or of subsequent movements, the Miocene beds occur on the northern flank of the Alps at a much greater height above the sea than on the southern, and have been much more upraised in the central than in the western and eastern Alps. Further, between the Lago Maggiore and the south of Saluzzo, Mesozoic rocks are almost absent from the southern flank of the Alps, and the Miocene beds are but slightly exposed and occupy a comparatively lowland country. I think it therefore probable that the second set of movements produced more effect on the German than on the Italian side of the Alps, producing on the latter a relative depression. In support of this we may remark that the rivers which flow from the Alps towards the north or the west, start, as a rule, very far back, so that the watershed of the Alps is the crest of the third range reckoning from the north, and the great flat basin of the Po is the receptacle for a series of comparatively short mountain rivers. These also take a fairly straight course to the gates of the hills, while the others change not seldom from the lines of outcrop to the lines of dip of the strata—a fact I think not without significance. To this rule the valley of the Adige in the eastern region is an exception. May not this be due to the remarkable series of minor flexures indicated by the strike of the rocks (Mesozoic and earlier) immediately to the west of it, which probably influences the course of the Adda, and can, I think, be traced at intervals along the chain as far as Dauphiné? Be this as it may, it is obvious that the generally uniform east-north-east to west-south-west strike of the rocks which compass the Alpine chain is materially modified as we proceed south of the Lake of Geneva, changing rapidly in the neighbourhood of Grenoble from a strike north-east to south-west, to one from north-west to south-east. This subject, however, is too complicated to be followed further on the present occasion. I will only add that the singular trough-like upland valleys forming the upper parts of some of the best-known road passes—as, for instance, the Maloya—which descend so gently to the north, and are cut off so abruptly on the south, seem to me most readily explained as the remnants of a comparatively disused drainage system of the Alps.

It remains only to say a few words on the post-Tertiary history of the Alps. We enter here upon a troubled sea of controversy, upon which more than the time during which I have spoken might easily be spent; so you will perhaps allow me to conclude with a simple expression of my own opinion, without entering into the arguments. That the glaciers of the Alps were once vastly greater than at the present time is beyond all dispute; they covered the fertile lowlands of Switzerland, they welled up against the flanks of the Jura above Neufchatel, they crept over the orange gardens of Sirmio, and projected into the plains of Piedmont. By their means great piles of broken rock must have been transported into the lowlands; but did they greatly modify the peaks, deepen the valleys, or excavate the lake basins? My reply would be, "To no very material extent." I regard the glacier as the file rather than as the chisel of nature. The Alpine lakes appear to be more easily explained—as the Dead Sea can only be explained—as the result of subsidence along zones roughly parallel with the Alpine ranges, athwart the general directions of valleys which already existed and had been in the main completed in pre-Glacial times. To produce these lake basins we should require earth movements on no greater scale than have taken place in our own country since the furthermost extension of the ice-fields. This opinion as to the origin of the lakes is, I believe, generally held to be a heresy, but it is a heresy which has been ingrained in me by some twenty years of study of the physiography of the Alps.

RECENT MORPHOLOGICAL SPECULATIONS

I.—*On Alternation of Generations*

IT is more than sixty years since Chamisso pointed out that in Salpa a solitary asexual individual produced a chain of sexual individuals by budding, the viviparous eggs in these becoming in turn the solitary form. This he made his type of *Alternation of Generations*.

Since his time the definition of this peculiar method of reproduction has been narrowed, and the alternation of a series of individuals developed from an unfertilised egg, *i.e.* parthenogenetically, and one or more generations of sexually produced young is now called *heterogamy*; the term *metagenesis* has been invented for cases of alternation of sexual and gemmiparous generations.

Few instances can be cited where the study of a single genus has brought out so many points of interest as in the case of the pelagic Ascidian, Salpa. Two points in the history of this animal still involved in controversy are the first phenomena of embryonic development, and the mutual relationship of the two forms, the solitary individual and the colony that swim united in a chain.

As regards the former matter, the fate of the egg and the origin of the nutritive structure known as the placenta present great difficulties.

While W. K. Brooks (*Bull. of Museum of Comp. Zool.*, Harvard University, iii.) believed that the egg undergoes a regular segmentation resulting in the formation of a gastrula, the cavity of which is divided by a transverse constriction into two chambers, one becoming the "placenta," Todaro (*Atti della R. Accad. dei Lincei*, Rome, 1875, 1880), on the other hand, stated that the solitary Salpa is the result, not of the division of the true ovum, but of the *follicular cells* inclosing it, and that during development, which takes place in a special part of the oviduct, the so-called uterus, a fold of the uterine wall forms a decidua reflexa comparable to that of mammals.

Salensky (*Zool. Anzeiger*, 1881; *Mittheil. d. zool. Stat. zu Neapel*, Bd. iv.) accounts for some of these conflicting statements by showing that great variety exists in nearly allied species, but he also declares that previous observations were often inaccurate. He states that the fertilised ovum divides but slowly, and only till the number of its segments reaches sixteen; and that probably it then entirely disappears, the tissues of the embryo being formed from a varying number of *follicular cells*. In some cases, as *S. bicaudata*, the so-called "decidua" is not represented. To this most exceptional method of development he gives the name of "follicular budding."

Now the theory that Salpa is an instance of the alternation of sexual and gemmiparous generations (*i.e.* of *metagenesis*), which was put forward by Chamisso and supported by the researches of Krohn, has been attacked by Brooks, who believes that the solitary Salpa (which he calls the *nurse*) is hermaphrodite, and gives rise by budding to a chain of males into each of which an egg migrates from the nurse. This view of course supposes that the solitary and chain forms belong to the same generation, they being, in fact, respectively the sexually and asexually produced offspring of one and the same solitary hermaphrodite Salpa. Todaro, on the other hand, states that, in the solitary adult, certain of the follicular cells surrounding the ovum give rise to no organs, but remain as cell-masses; and that from these the stolon is eventually developed. Hence the chain-Salpæ are developed parthenogenetically, and the nurse is an older sexless form, serving to nourish the sexually complete chain.

In Brooks' theory the main point is the migration of ova from the solitary individual into the individuals of the chain. In the light of a study of closely allied genera we find serious objections to this view. The fact on which it is chiefly based is that in the stolon when quite immature, we can trace the following organs: *a*, the outer tunic or epidermis; *b*, the pharyngeal cavity continuous with the pericardium; and *c*, two "club-shaped masses" of cells which lie on either side of *b*, and which soon resolve themselves into two lines of ova, one of which passes into the sinus system of each zooid. The discovery of undoubted ova in the stolon when the organs of the zooids are hardly indicated suggests, says Brooks, a migration from the nurse, which is therefore female.

Now we have, in direct opposition to this, an observation of Salensky's, that in some cases a second ovary is developed in the chain-Salpæ; and an indirect negation is entailed in the facts of gemmation in Pyrosoma, which is generally allowed to be a less modified form. Here we find the bud, when merely a protuberance on the mother, consisting of an epidermis derived from that of the mother, an "archenteric" cavity continuous with the endostyle, and a mass of cells which are derived directly from the "generative blastema." In this mass a single ovum can be seen quite as early relatively as in Salpa, and a second near the base supplies the secondary bud. Among the Composite Ascidians the case is similar; in Amourœcium the buds are cut off from the post-abdomen and consist of outer tunic, mesentery (that is, continuation of pharynx backwards), and two lateral masses in which germinal vesicles shortly appear; in Didemnium, also, although Kowalevsky traced the buds back to a condition much more nearly resembling the segmenting ovum, still even here the single ovum is one of the most conspicuous of the primitive organs. It is apparent that there is in the Tunicata a tendency to form buds at the expense of the three primitive layers, and that some advantage attends the early development of ova. Whether this is to avoid the danger of self fertilisation or not, it reaches its limit in Salpa, where the rudiment of the ovary only consists of one fully developed ovum.

A similar modification in the time of development of the ova has taken place in some of the Hydrozoa (Hydrella, Sertularia, &c.), where, as Weismann has pointed out (Abstract and Review by Prof. Moseley in NATURE, vol. xxix. p 114), the immature ova may be detected in the cœnosarc before even a rudiment of the bud appears.

The view which Todaro upholds seems also to be negatived by Salensky's observations. For if the solitary Salpa is developed by follicular budding, it is not remarkable that some of the cells should form an organ corresponding to the generative blastema of Pyrosoma, *i.e.* giving rise only to the generative cells.

If Salensky's facts stand the test of further observation, we have in Salpa not only a unique method of development but a unique alternation of generations, namely, of gemmation and parthenogenesis, only comparable to that of the Aecidiomycetes among plants.

In Pyrosoma, the individual developed directly from the egg is the "cyathozooid," and this remains rudimentary, giving rise to the first four ordinary individuals by budding. There is here an alternation of a single asexual form with numerous generations produced by budding, each of which becomes hermaphrodite.

According to Ganin, we have a precisely similar case in the Composite Ascidians, for he states that sexual organs only develop in the individuals produced by gemmation.

In Doliolum the ovum, as before, gives rise to an asexual individual, but the lateral and median buds which arise on its dorsal stolon do not become sexually mature. The former only serve to nourish and protect the latter (Grobben, *Arbeit. der Zool. Insti'. zu Wien*, iv.), from which a ventral stolon (stalk of attachment) grows out, bearing sexual individuals.

Outside the group of the Tunicata, true alternation of generation occurs in some Cœlenterates, some Annelids, some Cestodes, and possibly in the Trematodes.

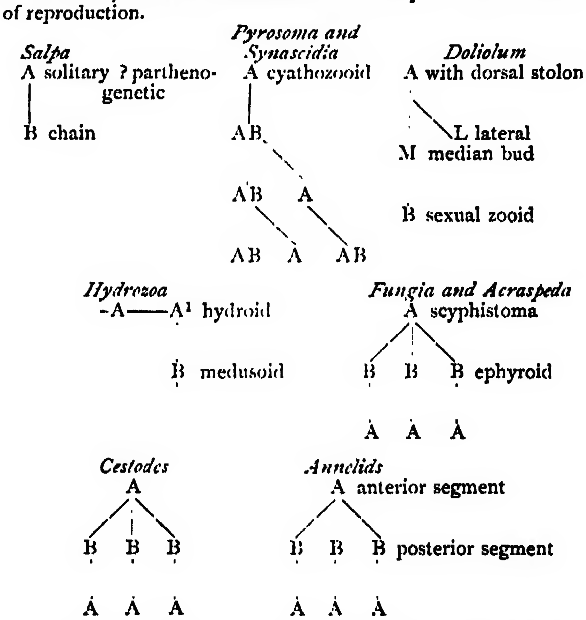
The alternation of hydroid and medusoid forms in many Hydromedusæ (Gymnoblastic and Calyptoblastic Hydroids and Hydrocoralla), all Acraspeda except Pelagia, and possibly Fungia among the Actinozoa, has been dwelt on in a previous paper in this journal by Prof. Moseley, and little range of modification occurs except in the extent of development of the medusæ.

In Cestodes the complicated metamorphosis has been mistaken for metagenesis, but it is only in those cases where the cystic worm develops a number of "heads" by gemmation, *e.g.* *Cœnurus cerebralis*, *Tænia echinococcus*, that metagenesis really occurs.

There is more uncertainty about the condition of affairs in the Trematodes, the ordinary view being that "the majority of the [illegible]s of a complicated metamorphosis, but in the coexistence of larval budding (giving rise to Cercariæ or a second generation of Rediæ) with true sexual reproduction there is in addition a true alternation of generations" (Balfour, "Comparative Embryology," vol. i. pp. 172, 173). Grobben (*loc. cit.*), however, has lately stated that the Cercariæ are developed not from a mass of cells produced by internal budding in the Redia but from an ovum developed parthenogenetically. This would place these phenomena under the category of heterogamy.

Among the Polychætes there exist in Syllis, Myrianida, and Autolytus undoubted cases of alternation of generations; but these are not of recent discovery, having been described by Quatrefages, Krohn, and A. Agassiz about 1850–1860 (Balfour, *ibid.*, i. pp. 283, 284).

A general comparison of the various ways in which reproduction is carried on within the limits of alternation of generations may be easily made by a series of diagrams in which A represents the asexual individual developed from the fertilised egg, B the sexual zooid, and A B those forms which carry on both methods of reproduction.



Heterogamy, which is not so common as metagenesis, has been the subject of very interesting memoirs by Adler and Lichtenstein. In a paper, "Ueber den Generationswechsel der Eichent Gallwespen" (*Jenaische Zeitschrift*, 1881), we have the result of Dr. Adler's work on "Gall-making Hymenopterous Insects," formerly described as belonging to eight different genera, namely *Neuroterus*, *Aphilothrix*, *Dryophanta*, *Biorhiza*, *Spathegaster*, *Andricus*, *Teras*, and *Trigonaspis*. He confirms the conclusions of Lichtenstein that certain species of the first four of these genera are stages in the life-history of certain species of the last four.

The gall wasps which in April leave the small round scale-like galls on the under surface of the leaves of the oak, have been described as *Neuroterus ventricularis*; but the parthenogenetic egg develops within a round soft "currant-gall" to a wasp named *Spathegaster baccarum*. The latter escapes in June, and differs from the Neuroterus in size, colour of the legs, and in the female in the number of joints in the antennæ. The eggs produced by the Spathegaster when fertilised develop within Neuroterus galls. A still greater difference exists between the two generations formerly called *Biorhiza renum* and *Trigonaspis crustalis*. Trigonaspis is 4 mm. long, winged, almost entirely black, with antennæ of 15 (♂) and 14 (♀) joints, while the Biorhiza is 1·5 mm. long, wingless, red-brown, and with 13 joints in the antennæ; the two forms live, moreover, in different kinds of galls. [illegible]ll these cases the alternation is direct. But among

Phylloxera quercus (Balbiani) migrates from *Quercus ilex* to *Q. sessiliflora.*

P. vastatrix, from the leaf-galls to the root of the vine.

Tetraneura rubra, from galls on trunk of elm to roots of dog's grass.

T. ulmi, from elm-galls to roots of maize.

Other less perfect examples of heterogamy, such as Cecidomyia and *Ascaris nigrovenosa,* are well known.

The current views concerning the probable origin of the phenomena of heterogamy and metagenesis may be roughly classed in two groups, one formulated by Leuckart and supported by Claus and Balfour, the other held by Salensky and Brooks.

Leuckart supposed that alternation of generations is a division of labour in regard to reproduction in which the two chief kinds of multiplication, sexual and asexual, are divided between different individuals and generations.

The other theory is that these phenomena are due to a modification of metamorphosis, Salensky also stating that "the connection between metagenesis and metamorphosis is much more easily seen in Tunicates than in other animals."

If in an animal undergoing a metamorphosis the larva acquired the power of producing other individuals by budding, we should have the larval form undergoing finally a change into the adult sexual form. At the same time it is obvious that this is not an indispensable condition; for the more individuals the larva produced the more incapacitated it would be for future sexual reproduction, so that in all probability there would soon be no development beyond the larval stage. W. K. Brooks, in a recent paper on the subject, alludes to a medusa, Cunina, the hydroid form of which is parasitic on the stomach of another medusa, Turritopsis. This hydroid produces medusæ by gemmation, but is itself finally modified into a medusa.

The contrast between this and the more usual case is thus :—

Cunina
Egg
|
{ Larva becoming adult } — { Adult }

Ordinary Forms
Egg
|
Hydra——Hydra——Hydra
| |
Medusa Medusa

Similarly in the Cestodes it is usually allowed that the Echinococcus stage consists in the production of a number of individuals in the larval state, not of adults differentiated to meet diverse methods of reproduction.

In such a form as Doliolum, and indeed generally among the Tunicata, there seems to be more difficulty attending this view. Gemmation does not result in the production of individuals like the gemmating zooid, which by growth become unlike it. The cyathozooid, or the Doliolum with dorsal stolon, not only do not become sexual after a metamorphosis, but they give rise to the ascidiozooid, a form with ventral stolon in no way comparable to the adult of which it is the arrested larva. It seems here more probable that the existence of two methods of reproduction perhaps taking place at slightly different times has led to the selection of two sets of individuals, one better fitted for gemmation, the other for sexual reproduction. We must then suppose that any influence acting for the modification of one generation is transmitted not to the next but the next but one.

[1] Huxley's distinction of true ova and pseud-ova appears not to hold.

THE PARIS ACADEMY OF SCIENCES

THE yearly public meeting of this body was held on Monda May 5, under the presidency of M. Emile Blanchard. T proceedings consisted mainly of a detailed statement of the awar made for prize essays or distinguished services rendered durii the year 1883 to the various branches of the mathematical ar natural sciences, useful arts, and industries.

In Mechanics the Extraordinary Prize of 6000 francs, establishe to encourage improvements of all sorts in the efficiency of tl French Naval Service was divided, as in previous years, among several candidates. For his "Studies on Marine Engines," no in course of publication, M. Taurines received 3000 francs, M Germain 2000, for his "Treatise on Hydrography," and Cap A. de Magnac 1000, for his "New Astronomic Navig tion," published in 1877. The Montyon Prize, in the same d partment, was also divided, half going to M. Léon Francq, fo his improvements in Lamm's steam traction engine, and half t Capt. L. Renouf, inventor of an instrument intended to simpli the observation of altitudes at sea, dispensing with the necessi of employing artificial horizons and enabling exact calculatior to be made without stopping the vessel under sail or steam. M Jacquemier, inventor of the kinemometer, dynamometer, an other useful appliances, gained the Plumey Prize; and M. Marc Deprez the Fourneyron, for his ingenious electric experiments o the Chemin-de-fer du Nord.

The Lalande Prize, founded by the illustrious astronomer t stimulate astronomical studies in France and abroad, was unani mously decreed to MM. Bouquet de la Grye, de Bernardières Courcelle-Seneuil, Fleuriais, Hatt, Perrotin, Bassot, Bigourdan and Callandreau, chiefs of the various French expeditions sent t observe the transit of Venus on December 6, 1882. In thi branch the Valz Prize was assigned to M. Stephan, Director o the Marseilles Observatory, and discoverer of about 700 nebulæ, the positions of over 500 of which he has carefully determined.

For his extensive labours in the field of Experimental Physics M. Henri Becquerel was rewarded with the Lacaze Prize, the only one given away in this department.

In Chemistry the Jecker Prize was secured by M. Etard for his numerous researches and publications on organic chemistry. M. L. Cailletet obtained in this branch the Lacaze Prize for his important researches on the liquefaction of gases, and especially for his success in, for the first time, demonstrating the possibility of liquefying all the so-called permanent gases.

In Geology the Grand Prize granted by the Minister of Finance for the best geological description of any region in France or Algeria fell to M. Fontannes for his long and successful researches in the Tertiary Basin of South-East France, mainly embodied in his "Stratigraphic and Palæontological Studies of the Tertiary Period in the Rhone Valley." An exceptional award of 2000 francs was also made in favour of M. Péron, author of an extremely important work entitled "Essay on a Geological Description of Algeria."

For his comprehensive monograph on Trichinosis, M. Joannès Chatin, Director of the Government Laboratory at Havre, obtained the Barbier Prize; and MM. G. Bonnier and L. Mangin the Desmazières Prize for their memoir on the "Respiration and Transpiration of Fungi," both in the department of Botany. In the same department M. Costantin was the successful competitor

for the Bordin Prize, awarded for the best solution of the following question proposed in 1879 by the Academy:—"Explain by direction observation and experiment the influence exercised by the environment on the structure of the root, stem, and leaves of vegetable organisms. Study the modifications undergone in water by land plants and those experienced by aquatic plants compelled to live in the air. Explain by direct experiments the special forms of some species of marine flora."

In Agriculture the Morogues Prize was gained by M. Duclaux for his great work on "Biological Chemistry," forming part of the "Chemical Encyclopædia" published under the direction of M. Fremy.

In Anatomy and Zoology the Grand Prize granted by the Minister of Finance for the best memoir on the "Histological Development of Insects during their Metamorphoses," as proposed by the Academy, was assigned to the young naturalist, Dr. H. Viallanes, for his "Researches on the Histology of Insects, and on the Histological Phenomena accompanying the post-embryonic Development of these Animals." In the same department the Bordin Prize was awarded to M. Grand'Eury, who, in two memoirs entitled "Carboniferous Flora of the Department of the Loire and Central France," and "On the Formation of Coal," deals satisfactorily with the "Botanical or Zoological Palæontology of France or Algeria," as proposed by the Academy to competitors for this prize.

Subjoined are some of the most important prizes proposed for 1884 and following years:

1884

BORDIN: General Study of Monge's Problem of Earthworks.

FRANCŒUR: Works or discoveries useful to the progress of the pure and applied mathematical sciences.

THE EXTRAORDINARY PRIZE OF 6000 FRANCS: Studies tending to increase the efficiency of the French Naval forces.

PONCELET: Awarded to the author of the most useful work in advancing the pure or applied mathematical sciences.

PLUMEY: For improvements in steam-engines or any other invention contributing most to the progress of steam navigation.

GRAND PRIZE OF THE MATHEMATICAL SCIENCES: For any important advance in the theory of the application of electricity to the transmission of force.

VAILLANT: Fresh researches on fossils made in any region which for the last quarter of a century has been little explored from the palæontological standpoint.

DESMAZIÈRES: For the most useful work on the cryptogamous plants.

GRAND PRIZE OF THE PHYSICAL SCIENCES: On the mode of distribution of marine animals along the French seaboard.

1885

DELMONT: To engineers, for the best work connected with the Department of Public Works (Roads and Bridges).

FOURNEYRON: Theoretical and practical study on hydraulic accumulators and their applications.

DAMOISEAU: Review of the theory of Jupiter's satellites.

GRAND PRIZE OF THE MATHEMATICAL SCIENCES: Study of the elasticity of one or several crystallised bodies from the experimental and theoretical standpoints.

BORDIN: Researches on the origin of atmospheric electricity, and on the causes of the great development of electric phenomena in thunderstorms.

L. LACAZE: For the best treatise on physics, chemistry, and physiology.

DELESSE: For a work on geological sciences, or, failing this, on mineralogical sciences.

MONTAGNE: For important works on the anatomy, physiology, development, or description of the lower cryptogamous plants.

GRAND PRIZE OF THE PHYSICAL SCIENCES: Study of the intimate structure of the tactile organs in one of the chief natural groups of Invertebrates.

BORDIN: Comparative study of the freshwater fauna of Africa, Southern Asia, Australia, and the Pacific Islands.

GAY: Measure of the intensity of weight by the pendulum.

CUVIER: For the most important treatise either on the animal kingdom or on geology.

PETIT D'ORMOY: Pure or applied mathematical sciences and the natural sciences.

1886

DE LA FONS MELICOCQ: For the best treatise on the flora of North France.

1887

CHAUSSIER: For important works on legal and practical medicine.

1893

MOROGUES: For the most useful work in stimulating the progress of agriculture in France.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, April 24.—"On the Relation between the Electrical Qualities and the Chemical Composition of Glass and Allied Substances." Part I. By Thomas Gray, B.Sc., F.R.S.E., and Andrew Gray, M.A., F.R.S.E., Assistant to the Professor of Natural Philosophy in the University of Glasgow, and J. J. Dobbie, M.A., D.Sc. (Edin.), Assistant to the Professor of Chemistry in the University of Glasgow. Communicated by Prof. Sir William Thomson, F.R.S.

This paper describes some further experiments as to the relation between the chemical composition of glass and its quality of resistance to electrical conduction through its substance.

The experiments were made on specimens of flint glass of different densities, made by different makers, and varying considerably in chemical composition. The method of experimenting was that described in Mr. T. Gray's paper on the same subject (*Proc. R. S.*, No. 222, 1882). Each of the specimens, which were in the form of globular flasks of nearly three inches in diameter, was filled up to the bottom of the neck with mercury, and immersed to the same level in mercury contained in an outer vessel. A wire dipping in the mercury within the flask was connected, without touching the table or any of the supports, to one terminal of a sensitive galvanometer of high resistance, and the circuit completed, through a battery of about 120 Daniell's cells, from the other terminal to the mercury in the outer vessel. (The galvanometer was well insulated, and was the high resistance astatic instrument described in *Proc. R. S.*, February 14, 1884.) The outer vessel, containing the flask, was immersed in a sand-bath which was heated by a Bunsen burner to temperatures above 100° C., and readings of the galvanometer taken at different temperatures, with precautions to insure that there was no error due to leakage. By means of a suitable reversing key in the circuit, the direction of the electrification, which lasted in each case about three minutes, was reversed between each pair of readings. From the observed deflections, and the constants of the galvanometer and battery, which were frequently determined, the resistance of the flask at each temperature could be calculated.

The results of the electrical experiments and of complete analyses of the specimens of glass are detailed in the paper, and show that the specific resistance of glass of the kinds experimented on increases with the percentage of lead contained in the glass and also with the density; and that further, as had been previously found by different experimenters, the resistance diminishes as the percentage of alkali present in the glass increases. The best specimen experimented on contained over 40 per cent. of oxide of lead, and had a density of 3·141, and a specific resistance at 130° C. of 8400×10^{10} ohms between two opposite faces of a centimetre cube. From this result, as it has been found by these and former experiments that the resistance is halved, over a considerable range of temperature, by an increase of temperature of about $8\frac{1}{2}$° C., the approximate resistance of the glass at other temperatures may be found.

The paper concludes with a short statement of further work which the authors have in hand with respect to the electrical qualities of glass and minerals.

Linnean Society, May 1.—Prof. P. Martin Duncan, F.R.S., vice-president, in the chair.—Messrs. Wm. Dennison-Roebuck and F. Newton-Williams were elected Ordinary Fellows, and Profs. E. Haeckel of Jena, A. Kowalevsky of Odessa, and S. Schwendener of Berlin, Foreign Members of the Society.—Mr. S. O. Ridley exhibited and made remarks on a series of drawings of sponges (and their spiculæ) and of Actiniæ drawn from the living objects, as obtained in Ceylon and forwarded by Dr. W. C. Ondaatje, F.L.S.—Prof. Jeffreys Bell also drew attention to sketches of living Ceylonese Comatulids sent by Dr. Ondaatje as an earnest of progress in researches on the marine fauna of that coast.—Mr. T. Christy showed the leaf of a China grass rich in fibre useful for textile purposes.—Mr. R. Bowdler Sharpe read a paper on a collection of birds from

the Bahr-el-Ghazal province and the Nyam-Nyam country in Equatorial Africa. The collection had been made by Herr Bohndorff, who had spent several years in travelling over the region in question, and who brought a native Nyam-Nyam with him to the Society's meeting. Mr. Sharpe gave descriptions of and remarks on new species and on little-known birds, some twenty-seven in all, these being of considerable significance in relation to their faunal distribution. He pointed out that Herr Bohndorff had apparently crossed the boundary line of two faunas, for most of the Nyam-Nyam birds assimilated to those known from the Gaboon and Congo territory; whereas those obtained in the Bahr-el-Ghazal and Nilotic region were allied to the avifauna of North-East Africa and partly of the Senegambian area. Among new species cited are *Crateropus bohndorffi*, *Sigmodus griseimentalis*, *Mesopicus strictothorax*, *Centhinochares intermedius*, *Pionias bohndorffi*, and others of equal interest.—Mr. R. A. Rolfe thereafter gave a communication on the flora of the Philippine Islands and its probable derivation. According to recent computation the phænogamic vegetation of the Philippines consists of 3564 species belonging to 1002 genera. Of 165 dicotyledonous orders 119 are represented, and of monocotyledons 25 out of 35; while the three gymnospermeæ, though nominally there, are poor in number. The proportion of vascular cryptogams to phanerogams is nearly one-eighth, chiefly ferns. Of these 52 species are not known elsewhere, a fact stamping individuality on the flora. The endemic phænogamic vegetation consists of 917 species, or a proportion of over one-fourth endemic, the dicotyledons showing one-third, the monocotyledons about one-tenth. The striking feature of the flora the large number of endemic species and the very small number of endemic genera. The flora approximates to that of the Malayan region, but very many typical Malayan genera—those even occurring on the neighbouring island of Borneo—are wanting in the Philippines. Taking into account the dominant Australian and Austro-Malayan features, along with numerous other data and reasoning, Mr. Rolfe infers that Mr. Wallace's idea of extinction of genera by submergence will not alone explain the present peculiarities of the vegetation. Mr. Rolfe looks upon the Philippines as truly insular in the essentials of their natural history, this not so much through their being an early separation from the Asiatic continent which has had a dip under the sea, as from their being largely of volcanic and geologically of somewhat recent origin.—Mr. Geo. Brook read a preliminary account of the development of the weaver fish (*Trachinus vipera*). In this he mentioned that the eggs had been laid in his aquarium at Huddersfield, the fish themselves having been kept alive therein over two years. He drew attention to the fact of there being a vitelline membrane present in the eggs of this fish, as well as in those of the herring; in contradistinction therefore to what is stated to be the case in osseous fishes generally. He also particularly referred to the persistent nature of the segmentation cavity, which is pushed round the yolk-sac concurrent with the development of the embryo from the blastoderm; and that it does not entirely disappear until the yolk is absorbed. Th circulatory system, according to Mr. Brook's researches, is very late in developing, no blood-vessels appearing until several days after hatching. In illustration of his paper he exhibited under the microscope preparations showing the segmentation stage, the embryonic shield, and commencement of keel, the early embryo third day before closure of the blastopore, and fourth-day blastopore and Kupffer's vesicle, also at the eighth day, and the newly-hatched embryo.—Dr. J. Millar and Mr. J. Jenner Weir were elected auditors for the Fellows, and Mr. T. Christy and Mr. H. T. Stainton for the Council.

Mathematical Society, May 8.—Prof. Henrici, F.R.S., president, in the chair.—Mr. J. Brill was elected a member, and Prof. Luigi Cremona, of Rome, Foreign Member, was admitted into the Society.—Prof. Cremona communicated, in French, a paper entitled "Sopra una trasformazione birazionale, del sesto grado, dello spazio a tre dimensioni, la cui inversa è del quinto grado." Dr. Hirst, F.R.S., welcoming the author, spoke in commendatory terms of the value of the communication.—The following papers were also laid before the Society:—Motion of a network of particles with some analogies to conjugate functions, by E. J. Routh, F.R.S.—On a subsidiary elliptic function, by J. Griffiths.—On the homogeneous equation of a plane section of a geometrical surface, by J. J. Walker, F.R.S.—On the "symmedian-point" axis of a system of triangles, and on another line which is connected with a plane triangle, by R. Tucker.

Chemical Society, May 1.—Dr. W. H. Perkin, F.R.S., president, in the chair.—The following papers were read:—On benzoylacetic acid and some of its derivatives (part i.), by W. H. Perkin, jun. For various reasons the author determined to examine carefully benzoylacetic ether with special reference to reactions in which the ketone group takes part. Full details of the preparation of this body, which boils at 265° to 270°, and gives a violet coloration with ferric chloride, are contained in the paper. When boiled with dilute sulphuric acid, it splits up into acetophenone, alcohol, and carbonic anhydride. The barium, silver, copper, and lead salts were prepared. The paper contains an account of the preparation and properties of the following bodies: Benzoylacetic acid, ethylbenzoylacetic acid, diethylbenzoylacetic acid, allylbenzoylacetic acid, the corresponding ethers and their decomposition products, and an investigation of the action of bromine on allylacetophenone.—The composition of coal and cannel gas in relation to their illuminating power, by P. F. Frankland. In this paper the author gives the results of a detailed examination of the gas supplied to some of the more important towns of the United Kingdom. The constituents which have been determined are the hydrocarbons absorbed by fuming sulphuric acid, carbonic anhydride, oxygen, nitrogen, hydrogen, carbonic oxide, and marsh gas. The results are compared with previous analyses in 1851 and 1876.—On selenium sulphoxide; on the reaction between hydrogen chloride and selenium sulphoxide; on selenium selenochloride, by E. Divers and Masachika Shimosé.—On a new form of pyrometer, by T. Carnelly and T. Burton. This consists essentially of a coil of copper tube, which is placed in the furnace, oven, &c.; through this coil flows a constant current of water; the temperature of the oven is estimated by the difference between the temperature of the water as it flows into and issues from the coil.—On fluorene, by W. R. Hodgkinson. During the fractional distillation of fluorene the formation of an orange-red substance was noticed; this seemed likely to be an oxidation product, and in the present paper the author gives an account of his attempt to isolate this body, which is rendered extremely difficult, as the substance decomposes when distilled in a vacuum, and is equally soluble with the hydrocarbons which accompany it.

Institution of Civil Engineers, April 22.—Sir J. W. Bazalgette, president, in the chair.—The paper read was on the comparative merits of vertical and horizontal engines, and on rotative beam-engines for pumping, by Mr. Wm. E. Rich.

EDINBURGH

Royal Physical Society, April 23.—Dr. Ramsay H. Traquair, F.R.S., president, in the chair.—Mr. Hugh Miller, of H.M. Geological Survey, read a paper on boulder glaciation and striated pavements, an abstract of which was given in these columns on May 1 (p. 23).—The President gave an outline of a paper by Mr. J. T. Richards, on Scottish fossil cycadaceous leaves contained in the Hugh Miller collection.—Mr. J. R. Henderson exhibited various mollusks and zoophytes from the Firth of Forth.—Mr. Henry Gunn, A.R.S.M., contributed a paper on the silver districts of Colorado (Leadville and San Juan). In the first portion of the paper, which dealt with the Leadville deposits, the author pointed out that within a limited thickness of from 700 to 1000 feet, typical representatives of Laurentian, Cambrian, Silurian, and Carboniferous rocks were to be found, and also indicated the influence which intrusive rocks had in the economic geology of the district, inasmuch as all the deposits occurred at the contact of the quartz porphyry with the limestones. Specimens illustrative of the ores mined in the district were exhibited, also some possessing unusual associations of mineral, a specimen showing granules of free gold in hard carbonate of lead attracting much attention from the fact that it was the only specimen ever discovered in the district exhibiting this association. Mr. Gunn exhibited specimens of tellurium ores of remarkable beauty, and a sample of zinc blende mined in large quantity in Pitkin County, which, contrary to the opinion generally held by miners, contained large quantities of silver. The second portion of the paper dealt with the San Juan district, and after indicating the peculiar disadvantages under which this district laboured for the first few years of its existence, proceeded to describe the geology of the district, which, he states, to be Trachyte overlying rocks of Carboniferous and Devonian age. The mineral is found in true fissure veins of great width, chiefly composed of quartzose matter, but usually carrying one or more gray streaks from two to six feet wide, composed of

galena, fahlertz, and sulphurets of silver and gold. Some of the mines produce beautiful filaments of native silver, and one of the specimens showed a very unusual association, viz. fine filaments of silver on gray copper.—The Secretary (Robert Gray, V.P.R.S.E.) exhibited a specimen of the Calandra lark (*Alauda calandra*) from the neighbourhood of Madrid, showing a peculiar malformation of both mandibles, which seemed to render it impossible for the bird to pick up its food. The specimen had been sent to him by Dr. A. C. Stark, and is to be deposited in the Edinburgh Museum of Science and Art.—Mr. Gray also reported the occurrence of at least three instances of the stock dove (*Columba œnas*) in Roxburghshire, and made some remarks on the distribution of the species in the border counties. This bird has now been found to be a regular visitant to the counties of Berwick, Dumfries, and Roxburgh, in all of which it breeds.—Mr. Harvie-Brown, F.R.S.E., F.Z.S., exhibited, with remarks, a specimen of the black redstart (*Ruticilla titys*, Scop.), taken last month on the Pentland Skerries, Pentland Firth. The specimen was a male adult, and is said to be the fifth of the species recorded in Scotland.

Mathematical Society, May 9.—Dr. Thomas Muir, F.R.S.E., president, in the chair.—Prof. Crum Brown delivered an address, interesting alike to mathematicians and to chemists, on the hypothesis of Le Bel and Van't Hoff.—Dr. Muir gave a preliminary account of a treatise on Determinants, published in 1825, and unknown to all writers on the history of the subject.

DUBLIN

Royal Society, April 21.—Section of Physical and Experimental Science.—Arthur Hill Curtis, LL.D., in the chair.—Notes from the Physical Laboratory of the Royal College of Science, by Prof. W. F. Barrett.—On the local heliostat, by G. Johnstone Stoney, D.Sc., F.R.S. This instrument was designed by the author many years ago, and made for him most satisfactorily by Messrs. Spencer and Sons, opticians, of Dublin, who have since constructed several reproductions of it for physicists at home and abroad, at the suggestion of one of whom it is now described. The instrument is in some degree a modification of Gambey's heliostat, but it differs from that apparatus by being simpler in its details, steadier, easier to use, and cheaper. These advantages are gained by sacrificing the generality of Gambey's instrument and providing only for stations within a limited range of latitude, usually about 10°, which, for example, enables one instrument to be used anywhere within the British Islands. Hence it has been called the local heliostat. The adjustment for latitude is of the simplest kind. After it is made, the instrument is to be levelled, and an arrangement based on the principle of the sun-dial enables it in about half a minute to be placed in the meridian. A polar axis is driven by a common clock at the rate of one revolution in twenty-four hours. To the upper end of this axis an arm is jointed, which, by a simple contrivance, can be pointed towards the sun, and which the clockwork, while in action, will then cause to follow that luminary. This arm trammels the mirror in the same way as in Gambey's instrument; and the reflected ray continues in the direction of a bar which can be placed in any azimuth and can be inclined up or down within reasonable limits. The direction of this bar, and with it of the reflected ray, can be readjusted, if necessary, in one or two seconds without disturbing the rest of the apparatus. The local heliostat has hitherto been made with mirrors about six inches by three for use in physical laboratories, but the design has been rendered so simple that it could be made at small cost with a mirror as large as a toilet glass, and driven by a cheap common clock. This would furnish an instrument which might be employed in physiological experiments on plants, in photography, and for any other purposes in which a large sunbeam in a fixed direction would be useful.—Dr. C. E. Fitzgerald exhibited Mr. P. Smith's model illustrating the conjugate movement of the eyes.

Section of Natural Science.—V. Ball, M.A., F.R.S., in the chair.—The following papers by D. Sharp, M.B., were communicated by Prof. W. R. McNab, M.D.:—(1) Descriptions of new genera and species of Hawaiian Coleoptera; (2) Catalogue of Hawaiian Coleoptera, with localities, distribution, and habits; (3) Topographical table of Hawaiian Coleoptera, with summaries, generalisations, and comments.—Prof. A. C. Haddon, B.A., F.Z.S., on the generative and urinary ducts in Chitons. The author discussed the various views as to the nature of the urinary ducts in Chitons. His own investigations supported Sedgwick's account as opposed to Haller's, and an oviduct was proved to exist in *Ch.* (*Trachydermon*) *ruber*, Linn.—Notes on some of the Irish crystalline iron ores, by G. H. Kinahan, M.R.I.A.—Addi-

[illegible] ing to phenomena [illegible] August 22 to 24, while the *Medea* was in the Sunda Straits. These embraced electrical effects, showers of sand and gravel, &c. At 2 p.m. on the 26th Capt. Thomson heard the first explosion; others succeeded every ten minutes. This geyser-like regularity was substantiated by all accounts received by the author. A column of dust arose to the westward immediately after the first explosion. Two observations enabled the height of this column to be computed. One gave seventeen, another twenty-one miles. The last included some doubtful factors, the observation being made three hours after first explosion. Further examination of the dust and pumice revealed hematite in thin blood-red flakes. The feldspars seemed divisible into two groups depending on optical and structural differences. Pyrites occurred not alone as an inclusion in the feldspars but also in the hypersthene. Optical tests rendered highly probable the presence of a triclinic pyroxene.

MANCHESTER

Literary and Philosophical Society, March 4.—H. E. Roscoe, F.R.S., president, in the chair.—A paper was read on the production and purification of gaseous fuel for industrial purposes, with the results of several large applications of a system, by W. S. Sutherland.

March 18.—H. E. Roscoe, F.R.S., president, in the chair.—Notes on the meteorology and hydrology of the Suez Canal, by Dr. W. G. Black, F.R.Met.S.

VIENNA

Imperial Academy of Sciences, April 24.—F. von Hochstetter, fifth communication to the seventh report of the Prehistoric Commission; on the tumuli at Froeg, near Rosegg (Carinthia).—K. Zulkorosky, on the aromatic acids as dye-forming matters.—W. Stephanie, on rotation of the moon.—T. Unterweger, on the aurora borealis.—T. Habermann and M. Hœnig, on the action of cuprum hydroxide on some sugars.—F. Berger, on the preparation of phenylcyanide.—E. Spiegler, contribution to a knowledge of the euxanthone group.—Contribution to a knowledge of diphenylglucetoxin, by the same.—T. von Hepperger, on the position and figure of isochrones in comets' tails.

VESTIGES OF CREATION

Vestiges of Creation. By Robert Chambers, LL.D. Twelfth Edition, with an Introduction relating to the Authorship of the Work, by Alexander Ireland. (London: W. and R. Chambers, 1884.)

ALTHOUGH the authorship of this interesting book has been for some time a somewhat open secret, the public avowal of it is to be welcomed for more reasons than one. The mystery which for so long a time has been allowed to hang over the subject was itself a mystery to explain. For any one reading the "Vestiges" could scarcely suppose that the free-minded, open-hearted, and fearless, truth-seeking spirit which looks out upon us in every page could be deterred by any motives of a petty or puerile kind from fixing the stamp of his name upon his work—at any rate in some of the later of the numerous editions through which the book passed. This mystery is now explained. In his brief introduction to this, the twelfth, edition, Mr. Ireland gives us the whole history of the matter. It seems that Mr. Chambers desired to conceal the authorship in the first instance for a variety of reasons, all of which were laudable. The chief among these was that "he was his brother's partner in a publishing business in which the rule had been laid down from the beginning of their co-partnery to avoid as far as possible, in their publications, mixing themselves up with debatable questions in politics and theology." After the author's death this brother continued to put his veto upon any declaration of the authorship, and so the secret was held close. About this time last year, however, Dr. William Chambers died, and left Mr. Ireland, as he says, "the sole surviving possessor of the secret." Previous to his death William Chambers expressed a wish that the secret should never be divulged; but as Robert Chambers had left the matter to the discretion of Mr. Ireland, this gentleman very properly undertook to keep the secret during the lifetime of the surviving relative, but refused to promise that he would do so in the event of his being left its sole repository. It is, therefore, to his sagacity and good feeling that the public are now indebted for the final clearing away of all the cobwebs which have been allowed to grow around this matter.

Of course the interest of the book itself is now purely historical. But if we were asked to indicate what is the feature which most strikes us on reading it from end to end, we should say, its power of clear and logical reasoning. The author is obviously a literary man, as distinguished from a man of science. But he is a literary man who is diligent in getting up his facts after the manner of a barrister preparing a case. He does not wait to examine his facts, provided that they make a decent show of probability, and produce a striking effect in his argument. As a consequence, even in this expurgated edition, we meet with a number of gravely erroneous statements. But the point to which we desire to draw attention is this. Although the writer every now and then admits erroneous statements of fact on insufficient evidence, and although as a consequence he every now and then runs after some will-o'-the-wisp hypothesis, he never loses his logical balance; but, after his chase is over, he returns to his main argument as little out of breath as when he started. This, we think, is no small praise. If Chambers constructs his argument barrister-wise, he does so merely for the sake of presenting to judgment everything that has any appearance of being a fact; and on the whole he exercises a wise discretion in his estimate of the comparative value of the facts as proved or unproved.

The interest attaching to this remarkable work being now purely historical, it is impossible to avoid contrasting it with the still more remarkable work by which it was so soon to be eclipsed. When we do so, we have brought home to us more forcibly than ever by how enormous an interval the mind of Mr. Darwin was separated from all contemporary thought on the origin of species. It is not merely that he happened to have shed upon the whole subject the new light which arose with the great conception of survival of the fittest. Indeed, while reading some of Chambers' broadly-stated and yet closely-reasoned views upon "the fecundity of nature ordaining that her creatures shall ever be pressing upon the verge of the local means of subsistence"; the consequent tendency of individuals to overflow into other areas, "thus exposing themselves to new influences"; the opportunity that is thus afforded to any variety happening to arise on the newly colonised area, and happening also to be adapted to these new conditions, to perpetuate itself by heredity (pp. 226-27);—when we read such passages, we are led to wonder that, having gone all round the hypothesis of natural selection, Chambers should not have gone through it. But where we find the immense contrast between him and Darwin is in the different manner wherewith they have treated even the same lines of evidence concerning the *fact*, as distinguished from the *method*, of evolution. If we compare the chapters on geological and geographical distribution, on the mental constitution of animals, &c., with the corresponding chapters in the "Origin of Species" and "Descent of Man," we are led to marvel, perhaps more than we have ever marvelled, at the gigantic grip of Mr. Darwin's mind. It is not merely that he had incomparably larger stores of facts to draw upon, that he was a man of science as distinguished from a man of letters, and so forth. It is rather that he was head and shoulders above everybody else in sheer mass and force of thought. We have now become so accustomed to walk easily through the jungles where he, like an elephant, has opened the way, that it is difficult for the younger generation to realise the state of matters before the elephant appeared. But in the "Vestiges of Creation" we have the vestiges of these former things. We here see a man of very unusual strength as a writer, with no small diligence in accumulating evidence, and well equipped with the implements of logical method; we see him fighting manfully with all his might to cut his way in the direction where he is profoundly convinced that the truth must lie; and yet we see that he is overwhelmed with the immensity of his task. His work is now well worth surveying, if only to make us realise the nature of the difficulties with which at that same time his great successor was contending.

But, leaving now this unavoidable comparison aside,

we shall give a few quotations from the book, in order to show at once the tone of thinking which more or less pervades the whole, and the pleasing style in which it is conveyed.

"There are some considerations on the very threshold of the question which appear to throw the balance of likelihood strongly on the side of natural causes, however difficult it may be to say what these causes were. The production of the organic world is, we see, mixed up with the production of the physical. It is mixed in the sense of actual connection and dependence, and it is mixed in regard to time, for the one class of phenomena commenced whenever the other had arrived at a point which favoured or admitted of it; life, as it were, *pressed in* as soon as there were suitable conditions, and, once it had commenced, the two classes of phenomena went on, hand in hand, together. It is surely very unlikely, *a priori*, that in two classes of phenomena, to all appearance perfectly coordinate, and for certain intimately connected, there should have been *two totally distinct modes of the exercise of the divine power*," &c. (p. 148).

"There is certainly no express reason to suppose that, although life had been imparted by natural means after the first cooling of the surface to a suitable temperature, it would have continued thereafter to be capable of being imparted in like manner. . . . We are rather to expect that the vital phenomena presented to our eye should mainly, if not entirely, be limited to a regular and unvarying succession of races by the ordinary means of generation. This, however, is no more an argument against a time when phenomena of the first kind prevailed, than it would be proof against the fact of a mature man having once been a growing youth that he is now seen growing no longer" (p. 168).

Notwithstanding this, however, the writer immediately begins coquetting with a number of very seductive facts and considerations in favour of spontaneous- or, as he more correctly terms it, "non-parental generation." In particular he lays great stress upon the "Crossian experiment" of producing acari by the action of a voltaic battery on a solution of silicate of potash. And here we have a very good special illustration of the difference between Chambers and Darwin. The former, as a literary man, states the experiments, weighs the evidence which they yield, and, without actually accepting the fact as proved, is on the whole strongly disposed to believe it. The latter, as a man of science, would have spent a lifetime in verifying so all-important a fact, even if the evidence of it had appeared to him of but a tenth part of the weight that it appeared to Chambers. Here, however, it is but fair to Chambers, as a literary man, to say that he does not in this place, or anywhere else, attach more than its due value to the evidence of any alleged fact. He merely gives the evidence for what it may be worth, and then passes on. Therefore he is careful to make it clear that whether or not all the considerations which he adduces in favour of "non-parental generation" are valid, the question of its actual occurrence is really a side issue, and does not affect the course of his general argument in favour of the evolution of species by way of "parental generation." This clearness of logical view is further and particularly well displayed in his consideration of Lamarck's theory touching the causes of the evolution of species: although Chambers is exceedingly anxious to find these causes, so that it might "appear as if the clouds were beginning to give way, and the light of simple, unpretending truth were about to break upon the great mystery," yet he critically puts his finger upon the weak points of the theory in question, and ends by dismissing it as inadequate to explain the facts (p. 233 *et seq.*).

One other quotation may be given as an example of the general common sense which the writer every now and then pours out, like a viscid secretion, wherewith to entangle and render helpless his opponents.

"It may be well to mark the credulity to which the adherents of immutability must here be reduced. They must believe that the Creator, having a particular regard to the fact of molluscan shells lying useless on the shore, formed, by special care or fiat, a family of crabs to occupy them. They must believe that the roughness of the caudal appendages, the development of suckers along the abdomen, the reduction of the two hind pairs of limbs, and the left pincer-claw, were all subjects for this special care, and were beyond the power of what an eminent geologist calls 'vulgar nature.' Surely the *Deus ex machinâ* was never more remarkably exemplified. See, on the other hand, how these facts are accounted for on the development theory. According to this new light, the hermit-crabs are simply a portion of some greater section of the crustacean class. Their peculiarities are modifications from the parent form, brought about in the course of generations, in consequence of an appetency which had led these creatures to seek a kind of shelter in turbinate shells" (p. 54).

It only remains to say that this, the no doubt final edition of the "Vestiges of Creation," is very prettily got up, and leaves nothing to be desired as to printing, &c. We feel, however, that it would have been well worth while to have had the reprint edited by some competent naturalist, who might have inserted footnotes to warn the general reader against the numerous pitfalls which are to be encountered on matters of fact. As it is, the general reader cannot possibly know what he is to accept as scientifically-established truth, and what he is to reject as superseded error. This we think is a pity in the interests of the book itself, because during its author's lifetime the successive editions were successively brought up to date in the matter of keeping pace with the progress of science. Lastly, in the appendix, written by the author himself in reply to criticisms, we must not fail to note the magnanimous temper, dignified style, and forcible reasoning, which contrast so favourably with the opposites of these things in the quotations which he has occasion to make from the more celebrated among his critics.

GEORGE J. ROMANES

NATTERER'S BRAZILIAN MAMMALS

Brasilische Saugethiere. Resultate von Johann Natterer's Reisen in den Jahren 1817 bis 1835. Dargestellt von August von Pelzeln. (Wien, 1883.)

THE collections of the celebrated Brazilian traveller and naturalist, Johann Natterer, owing to his untimely death shortly after his return to Europe, lay almost unnoticed for many years in the Imperial Cabinet at Vienna. At length Herr August von Pelzeln, after several years' unremitting study of the unrivalled collection of birds, published in 1871 his "Ornithologie Brasiliens"—well known to ornithologists as one of the most important authorities on the Brazilian avifauna. More recently the same laborious naturalist has devoted his attention to Natterer's mammals, and in the memoir now before us, of

which the second part has just been issued, has given us an excellent summary of Natterer's discoveries in this class of animals.

During his ten journeys in the Brazilian Empire (of which the first was commenced at Rio in November 1817, and the last terminated at Parà in September 1835) Natterer collected no less than 1179 examples of mammals, all most carefully prepared and accurately labelled, with notes of sex, colours of soft parts, date, and locality. These are referred by von Pelzeln to 205 species, 73 of which were new to science when first obtained by this unrivalled collector.

Natterer had planned a general work on the mammals of Brazil, in conjunction with Andreas Wagner. After the former's untimely death in 1843, Wagner published descriptions of the new genera and species in Wiegmann's *Archiv* and other periodicals, and introduced notices of them into his well-known supplement to Schreber's "Sangethiere." But we have now for the first time a complete systematic account of the whole of Natterer's collection with exact localities.

As might have been expected, the dense forest-region mostly traversed by Natterer was especially productive of Quadrumana—the American group of this order being exclusively arboreal in their habits. No less than 265 specimens of American monkeys were obtained, referable to 45 species, 4 of which were new to science. Of Chiroptera, Natterer procured examples of 48 species, of which at least 25 were first discovered by him. It should be also noted that the very singular structure of the stomach of the bloodsucking *Desmodi*, first made known by Prof. Huxley in 1865, was, as is testified by his note-books, previously discovered by Natterer in 1828!

The Carnivores are not so numerous in the Brazilian forests as the two preceding orders. Only 17 species were met with by Natterer, and only one of these (*Lutra solitaria*) was first made known to us by his specimens. The Rodents, on the other hand, are very abundant in species as in individuals in this part of South America. Not less than 50 species are represented in Natterer's series, whereof 24 were previously unknown to science.

The Ungulates are not abundant in South America, the true Ruminants being only represented by some peculiar forms of the deer family (Cervidæ). Of these Natterer obtained examples referable to 5 species. Besides the deer the only Ungulates met with were a tapir (*Tapirus americanus*) and the two well-known species of peccary.

Of the Sirenia, Natterer met with a manatee high up the stream of the Amazons, in the Rio Negro, Rio Brancho, and Madeira, and maintains in his notes that the species which inhabits these far inland waters is quite different from the *Manatus americanus* of the South American coast. Natterer called it *Manatus inunguis*, from its nailless fingers, and sent home to the Imperial Cabinet of Vienna three complete specimens and several skulls. Of the Cetaceans, Natterer met with two species of dolphin in the Amazons and its tributaries. *Inia amazonica* was found in the Guaporé and Madeira, and two examples obtained, and a head of *Steno tucuxi* was brought home from Barra de Rio Negro. Interesting notes are given on the structure of both these little-known animals.

We now come to the Edentata, which, as is well known, are well represented in the Neotropical Region by the three families of sloths, armadillos, and anteaters. Of each of these peculiar forms Natterer obtained a fine series. Among the sloths the two-toed *Cholopus didactylus* was met with on the banks of the Rio Negro and its tributaries, while of the three-toed genus *Bradypus* examples were collected which are referred by Herr von Pelzeln to five species. Of armadillos, Natterer obtained examples of five species, including the giant *Cheloniscus gigas;* he likewise procured specimens of all the three known species of anteaters.

South America is also rich in the smaller opossums, which constitute the only family of extra-Australian Marsupials, and amongst them this assiduous collector reaped a rich harvest. Of 18 species of which he sent home specimens not less than 11 were previously unknown to science, and were mostly described by Andreas Wagner under Natterer's manuscript names. It may, indeed, be safely affirmed that no naturalist, unless our countryman, John Gould, in the case of his celebrated expedition to Australia, be a possible exception, has ever been equally successful with Johann Natterer in discoveries amongst the higher classes of animals, and it is probable that no future naturalist, however great be his industry, will ever surpass him in the number and variety of his discoveries or in the excellence of his specimens.

OUR BOOK SHELF

A Treatise on Chemistry. By H. E. Roscoe, F.R.S., and C. Schorlemmer, F.R.S., Professors of Chemistry in the Victoria University, Owens College, Manchester. Vol. III. Organic Chemistry, Part II. (London: Macmillan and Co., 1884.)

THE first part of this volume, treating of the hydrocarbons of the paraffin series, and the alcohols, ethers, bases, acids, &c., derived therefrom, has already been reviewed in this journal (vol. xxv. p. 50). The part now under consideration treats of a large number of compounds derived from the di-, tri-, tetra, and hex-atomic alcohol-radicals, and from the monatomic alcohol-radicals of the series C_nH_{2n-1}; also of the carbohydrates, sugar, starch, gum, cellulose, &c., and of the furfuryl, meconic acid, and uric acid derivatives. Many of these bodies, *e.g.* the carbohydrates, and oxalic, lactic, malic, tartaric, citric, and uric acids, are of great importance as constituents of vegetable and animal organisms, and for their applications in arts and manufactures. The extraction and purification of sugar, from the cane and from beet, are clearly and fully described in this volume, and illustrated by excellent woodcuts of the apparatus and machinery used; also the estimation of sugar in juices, &c., by the optical or polarimetric method. Descriptions and illustrations are also given of the manufacture of starch, of the uses of cellulose in its various forms, cotton, flax, hemp, &c., and of the manufacture of paper.

Altogether the part now under consideration forms a very valuable portion of Roscoe and Schorlemmer's "Treatise," and we hope that the publication of the remaining parts—which will treat of the benzene-derivatives or aromatic bodies, and of the proximate constituents of the animal organism—will not be long delayed. The portions already published afford a guarantee that the volume when finished will form one of the most complete treatises on Organic Chemistry yet published in the English language.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Geology of the Malayan Peninsula

IN some geological excursions made recently in the State of Perak, I met with some curious facts which may be of interest to many of your readers. I made boat journeys down the Perak River from Enggor to the mouth, then back again up the valley of the Kiuta, and then returning to the mouth of the Kampar, went up that stream as far as boats can go. The main chains dividing these ranges are all granitic, rising to peaks generally over 3000 but sometimes over 7500 feet high. The ranges are flanked by Lower Limestone ridges, forming detached hills about 1500 feet in elevation. The summits of these hills, as well as on the flanks, are pierced with caves, which contain a ferruginous clay with stream tin. The latter is evidently derived from granite, but as the limestone hills are quite isolated, and some miles away from the source of the ore, the denudation of the country must have been very great. Some of the caves with tin sand are 1000 feet above the plain, and have to be approached by steps cut in the face of a precipice. These small mines are rich enough to attract a few Malays and Chinese, who are the only inhabitants. The country is otherwise a dense jungle. The limestone is crystalline, without a trace of organism, though lines of stratification can still be traced. Tin is also found in the drift at the base of these hills, entangled as it is in the pinnacles and peaks of the underlying limestone.

There is evidence of extensive denudation in both the granite and limestone. There are no signs of any recent upheaval in any of this country, nor, as far as I have seen, anywhere in the Malayan Peninsula, from Keddah to Johore. The country is rich in tin, which has been only partially worked.

There is a palæozoic sandstone clay slate or gneissose formation lying between the limestone and granite. It is much decomposed, and gives rise to a red clay which goes generally by the name of laterite. It is not of great thickness, but is widely represented by outliers at the base of the main ranges, often capping small detached hills. At the junction of this rock with the granite is in my opinion the place where the great deposits of tin have taken place. Wherever such outliers have been denuded away the resulting drift has always been noticed by me as richest in stream tin. On such drifts are the richest mines of Perak, notably Larut, Kamunting, and Assam Kumban. I dont think this palæozoic formation has been previously noticed, but indeed the country is but little known geologically. The slates are very like the Ordovician rocks of Australia, in which so much gold has been found. J. E. TENISON-WOODS

Thaiping, Perak, April 17

The Marine Biological Station and a Coast Survey

ALLOW me to say in reference to your article advocating a Biological survey of the British coasts, that you are quite right in supposing that such a survey falls within the scope of this Association. As a first step in the direction of such a survey the Association proposes to establish a dredging station and observatory on the south coast. Later it will, it is to be hoped, be able to establish or to cooperate in the establishment of additional dredging stations on various parts of the coasts of the United Kingdom, and thus gradually complete a *thorough* (not a superficial) survey such as is needed. The Association will no doubt seek the aid of the Government when the proper time for doing so arrives. E. RAY LANKESTER

Secretary (*ad interim*) of the Marine Biological Association

Atlantic Ice and Mild Winters

THE influence of the Gulf Stream in ameliorating the climate of the United Kingdom and of the north-west corner of Europe up to 71° of north latitude is so well known and so generally acknowledged that no comments are required; but can we discover any force sufficiently powerful by which this great heating power may occasionally be so largely augmented as materially to influence our usual winter temperatures, by bringing to our shores not only a larger flow of warm water, but also impelling it to strike or come into closer contact with our coasts further to the south?

I have, in a desultory way, for a series of years noticed that as a rule mild winters in England were associated with much ice extending far south in the Atlantic. The past winter is a striking example of this. Floe-ice has been more than once met with by steamers in lat. 40° N. and in about the same degree of west longitude, as nearly as possible midway between New York and Ireland, and in the direct ship track between Jamaica and Liverpool. These conditions indicate an Arctic current of very much increased volume, extending something like 400 miles south and an equal or greater distance east of the position given to it on any of the current charts I have examined.

The natural effect of so large a flow of cold water from the north meeting the Gulf Stream at right angles would not only be to deflect the latter to the southward of its usual course, causing it to strike our shores further south, but also in much greater volume, because a larger supply is required to replace the increased quantity from the Arctic

The only specially cold winds we have had in the past winter and spring have been from the east, with one or two brief exceptions, when there were gales from west and north-west, during which the air, after leaving the Arctic current, *may have* passed so rapidly over the Gulf Stream that it had not time to acquire any great increase of heat.

As was to be expected from the extra quantity of ice on the west side of the Atlantic the winter weather was unusually cold and changeable in Canada and the United States, varying with the direction of the winds.

The meeting of the Arctic current and Gulf Stream has no doubt been seen thousands of times. I had the good fortune to witness it only once, and it reminded me—but on a far grander scale—of two great rivers having waters of different colours, joining each other at right angles, or nearly so, as I have noticed with the McKenzie and some of its tributaries.

We were coming from Portland (February 1860), and our excellent captain had kept far south of the usual track, to avoid ice, so that for several days we were steaming *in* or at the edge *of* the Gulf Stream. The meeting of the two currents with their eddies—miles wide—was clearly defined, the water to the north being beautifully clear and blue, whilst to the south it had a brown colour with a thin film of haze over it. As we crossed the eddies or "swirls" of current, temperatures were carefully taken, that of the clear water being many degrees lower—I have forgotten the exact difference—than the brown or Gulf Stream.

Probably this whole question may have already been gone into and fully discussed by others; if so, the details have not come under my notice. My chief object is to attract the attention of those who are much better qualified to deal satisfactorily with this interesting subject than I can pretend to be.

4, Addison Gardens, May 10 JOHN RAE

Right-sidedness

IN NATURE for March 20 (vol. xxix. p. 477) Mr. Wharton and Dr. Rae criticise my letter of the 13th on right-sidedness. In writing that letter I had no intention of starting a new subject, but only to remove one source of confusion from the subject of bias in walking. But since the subject is started, I will say a few words in reply.

Neither Mr. Wharton nor Dr. Rae seem to be perfectly normally constituted. Dr. Rae is left-handed, indeed left-sided, by inheritance (I suppose), and right-handed in some things by education. In his case, therefore, the phenomena are more complicated, but there is nothing at all inconsistent with my view or at all different from what I would expect.

Mr. Wharton is near-sighted; his two eyes are of different focal length, and his *left* eye is *much the stronger*. And yet "by unconscious preference" he uses the right eye for the microscope or telescope. Is it possible to have a stronger confirmation of my view?

But he says that if right-sidedness has its cause in the brain, then, since I am right-handed, I ought to be left-eyed, for paralysis of the right side is attended with blindness of the left eye, and *vice versâ*. Is this true in all cases? If Mr. Wharton would prove it, physiology would owe him a deep debt. We all

know the complex and therefore delusive and often apparently contradictory character of the phenomena resulting from lesions of the brain, but I think the weight of experimental evidence (and surely this is more reliable than pathological) is the other way. Experiments on pigeons and dogs ("Dalton's Physiology," pp. 430 and 454) seem to show that lesions of the brain affect the opposite eye as well as the opposite side of the body. Anatomical structure also would lead us to expect this, for the fibres of the optic tracts cross over in the chiasma, in birds completely, and in mammals largely. But even if it were otherwise, I do not see that the question is materially affected. If right-sidedness is inherited, there must be, or must have been, some advantage in it; and there is no reason why inheritance should not have affected different sides of the brain for hand and for eye, if such were necessary to bring about the result.

Again, Mr. Wharton has the singular idea that because Europeans, who are a right-handed people, write from left to right, therefore Eastern nations who write from right to left must be left-handed! Obviously this does not follow. Many right-handed motions, such for example, as striking with a whip are from right to left, so that the contrary stroke, on account of its unfrequency, is called *backhanded*.

Lastly, Mr. Wharton alludes to the rules of boxing. The left hand is used mostly for striking, and the right for guarding. It would be well if some one acquainted with the subject would give us its history. My impression is that the present practice is comparatively recent, perhaps forty to fifty years old, and that formerly the right hand was used mostly for striking, and the left for guarding. I think, further, that even now the left is used more for feints and lighter blows, while the right is reserved for favourable opportunities to plant decisive blows.

Berkeley, Cal., April 23 JOSEPH LE CONTE

Dark Transit of Jupiter's First Satellite

ON May 18, at 8h., on observing Jupiter with my 10-inch reflector, p. 252, I saw three very dark spots—one near the planet's centre, and two others not far advanced upon the east limb. These I took to be the shadows of satellites, and on reference found that the shadows of Satellites I. and II. were really upon the planet; also Satellite I. itself. The latter was evidently the spot near the centre of the disk, and it appeared almost equally as black as the shadow. The satellite was situated close to the equatorial white spot, and in point of fact was projected upon the north-east borders of that object. The latter was estimated on the central meridian at 8h. 5m., so that its longitude, computed on the diurnal rate of $878°\cdot46$ (= rotation of 9h. 50m. 7·42s.), was $94°\cdot3$.

When near mid-transit, Satellite I., as regards its visible aspect, could hardly have been distinguished from its shadow, and I believe the very dark appearance of the satellite on this occasion to have been somewhat exceptional; for though I have observed a considerable number of its transits, I never saw it nearly so dark before. Bristol, May 19

The Remarkable Sunsets

A COPY of NATURE (vol. xxix. p. 149) just received here contains an article on "Remarkable Sunsets" which were seen in all parts of the world during the latter days of November and the early days of December. It may interest your readers to know that precisely similar sunsets to those described in the paper referred to above occurred here for several days in December. The "rosy pink after-glow" immediately succeeded the sunset, and lasted from ten to fifteen minutes. The phenomenon considerably scared the Chinese, who feared it portended some evil to the Emperor. The winter has been remarkably mild and dry; the first fall of snow, a very heavy one, took place on March 1. This region is volcanic; we have occasional shocks of earthquake. ARTHUR SOWERBY

T'ai Ynen Fu, Shansi, North China, March 5

"Notes on Earthworms"

REFERRING to Mr. Hughes' communication to NATURE of May 15, p. 57, I myself to-day saw a small worm pursued by a black insect, also evidently the larva of one of the Carabidæ. I was attracted by observing the worm emerge from the ground and hurry quickly away. When about five inches from its burrow the larva came out of the same burrow, and briskly followed in a zigzag course, until it overtook its prey, which it then seized near the tail end and dragged under some loose earth. No doubt the worm had been pursued underground, and was endeavouring to make its escape. E. A. SWAN

224, Camberwell New Road, May 17

The Recent Earthquake

IN p. 57 of the last number of NATURE notice is taken of the lack of observation on the late earthquake in Central Kent, Surrey, or Sussex. In Tonbridge we have known of three instances in which it was certainly felt. On the morning of April 22 a lady in bed in a room on the first floor felt a push from the foot of the bed so strong that she asked her little girl, who was in the room, why she was shaking it so, which of course the child denied—the bedstead being of iron and too heavy for her to have moved; the vallance at the head of the bed swayed to and fro. The second instance we heard of was an Indian officer, who felt it, while standing leaning against his mantelpiece, directed about from north-north-east to south-south-west. The third instance was an invalid lady in bed on the first floor.

Animal Intelligence

ONE night a loud knock was heard at the back door, and as the door could not be reached by any one outside the house except by getting over the garden wall, some alarm was caused. On the knock being impatiently repeated, the door was opened, and the cat ("Mrs. Muffins") walked in with great dignity. Since then she has never failed to make known her presence in the same way, always waiting after the first knock. Some weeks elapsed before it was ascertained how the knocking was produced, but at length it was discovered that a slip of wood which runs down the side of the door was loose at the bottom; this slip she pulls out with her paw, and then allows it to rebound. She is a very affectionate mother. Some time ago her mistress, by accident, hurt her kitten. "Mrs. Muffins" walked up to her and gave her two or three sharp slaps on the dress. To-day the same thing has occurred; but on this occasion, as the servant was the offender, "Mrs. Muffins" followed her into the kitchen to chastise her. I may also add that she has shown great intelligence in making her wants known to her friends.

E. A. LONERGAN

AGRICULTURE IN THE UNITED STATES[1]

WE may learn many a good lesson by observing the admirable manner in which the various Boards of Agriculture discharge their duties in the United States. With a sound discretion the mutual influences of geology and agricultural practice are prudently considered in association with the investigations of the chemist and the records of the Census Office. In these respects the various States are greatly in advance of anything provided in the United Kingdom. We have our Geological Survey most carefully conducted, and the maps showing the solid geology of the country are excellent. In addition to these we have another series of geological maps showing the drifts covering up these rocks, but at this point we cease to follow the example set us in the United States. Aided as each individual State is by a series of experts, such as the State Botanist, the State Geologist, the State Entomologist, the State Chemist, and similar officials, we thereby find most valuable help rendered to the agriculture of the country. This assistance is rendered more effective by reason of the concerted action by which it is so generally characterised. Each scientist views any given subject from his own special standpoint, and the great advantage of concerted action is the more mellowed judgment which is thereby secured.

In the Report before us we have one of those happy blendings of science and practice which is so well calcu-

[1] "Geological Survey of Alabama, embracing an Account of the Agricultural Features of the State." By Eugene Allen Smith, Ph.D., State Geologist.

lated to benefit the district dealt with, and which, instead of insulting the practical man, gives him information which he gladly utilises. The Report commences with a general discussion upon the composition, mode of formation, and the properties of soils, and the changes produced by cultivation. In the second section, soil in its relation to vegetation is somewhat elaborately dealt with. In the third section, soil in its relations to animal life is very completely presented to the reader's attention. The question of the absorptive powers of soils is ably dealt with. "As to the cause, opinions vary, but closer study of the phenomena of absorption have led back to the pretty general acceptance of the explanation originally offered by Way, which, as expressed by Mayer ('Agrikultur Chemie'), is as follows:—'We find in the soil easily decomposable double silicates, the exact composition of which is unessential, which, along with alumina, always contain some other base, an alkali or an alkaline earth, or even several of these bases at the same time. These silicates have the property, under certain conditions, of exchanging their accessory ingredients (not the alumina). The artificial silicate of Way had the composition of a zeolite, and it remained only to experiment with naturally occurring zeolites, which was done by Eichhorn, Mulder, and others, with the result of showing . . . that they all possess the power of exchanging a portion of their original content of lime or soda for an equivalent of potash or ammonia; in other words, of absorbing the latter bases. . . . According to Mulder . . . while the fertility of soil does not depend exclusively upon these zeolites, yet its chemical activity is altogether determined thereby.'" These comments are the more noteworthy because there has been a tendency amongst some chemists to undervalue the importance of Way's discovery, but the testimony of practice is too strong for it to be altogether ignored.

An exceedingly important connection is shown between the production of cotton and the systems of management pursued in Alabama. Speaking of the Great Cotton Belt of Alabama, the Report points out that the soils upon this belt have been largely exhausted by improvident culture, cotton being planted year after year upon the same soils, without any attempt being made to maintain the fertility by the use of manures. In other parts of the State where cotton is produced a selection is generally made of the better soils, rotation of crops is more generally practised, and in some sections fertilisers are in more general use. This is largely occasioned by the relative proportions of the population and the capital they have at their command.

"The system of credits in the large cotton-producing regions prevails to such an extent that the whole cotton crop is usually mortgaged before it is gathered, and when we consider that the prices charged for provisions are at least 50 per cent. higher than regular market rates, . . . it will need very little calculation to show that the labourer will have the chances too greatly against him, even to be out of debt to his merchants, when he relies solely upon this crop to provide the money, and the exorbitant interest on the money advanced is not likely to be lessened so long as the merchants' risks continue to be as great as they are. Where the blacks are in excess of the whites there are the originally most fertile lands of the State. The natural advantages of the soils are, however, more than counterbalanced by the bad system prevailing in such sections, viz. large farms rented out in patches to labourers, who are too poor and too much in debt to merchants to have any interest in keeping up the fertility of the soil, or rather they lack the ability to keep it up, with the natural consequence of its rapid exhaustion and a product per acre on the best lands in the State lower than that which is realised from the very poorest. Where the two races are in nearly equal proportions . . . there is found the system of small farms, worked generally by the owners, a consequently better cultivation, a more general use of commercial fertilisers, a corresponding high product per acre, and a partial maintenance of the fertility of the soils."

The entire Report is literally crowded with interesting and most important details, such as skilled experts are likely to formulate for the guidance of higher officials and for the assistance of those engaged in the cultivation of the land. The well-organised system existing in the United States, whereby the causes of failure and success are rendered prominent, is doing great service to that country, for they clearly recognise the truth that the advancement of agriculture is a national duty, because just in proportion as additional wealth is thus created within the States, so do the people generally participate in the advantages thus secured.

BIRD SKELETONS[1]

THE author of this important work, shortly after his return from his explorations in New Guinea and the Moluccas, was appointed Director of the Royal Zoological Museum at Dresden, and under his care the last-named museum is fast becoming one of the leading institutions in Germany. During his travels in the East Dr. Meyer appears to have amassed a considerable amount of material for his projected work on the skeletons of birds, and now that five parts of the "Abbildungen" have appeared, we think it well to draw the attention of English naturalists to it, as it will undoubtedly prove to be one of the most interesting osteological works yet attempted. The skeletons are all contained in the Dresden Museum, and Dr. Meyer proposes to carry on the work until his material becomes exhausted; but we trust that all ornithologists who can aid the author in his excellent enterprise will not fail to do so.

The works on the osteology of birds are not numerous, and this important portion of ornithological study has been too much neglected and systematically overlooked. The chief English work has been the "Osteologia Avium" of the late Mr. Eyton, and there are, of course, Prof. Owen's well-known memoirs on the *Dinornis* and its allies, on the Great Auk, and a few scattered representations of skeletons here and there. France can boast of Prof. Milne-Edwards's splendid volumes on fossil birds in comparison with recent forms, as well as the fine series of illustrations in the "Histoire Naturelle de Madagascar" of M. Grandidier. In Germany Prof. Selencka, of Erlangen, commenced, in Bronn's "Classen und Ordnungen," a systematic treatise on the osteology of birds, but unfortunately he discontinued this useful work after the issue of a few parts. Dr. Meyer's labours therefore deserve the acknowledgment of all scientific men as being an attempt to fill up a gap in our knowledge of birds. There are probably eleven thousand species of birds described up to the present time, but the osteological characters of only a very small proportion of them have been noticed, and a very inconsiderable number of the three thousand genera have been illustrated. As Dr. Meyer only figures those species which have not been before represented, each illustration represents a new fact for science, and we trust that he will be able to continue to add to the already rich materials at his command, and bring to a successful conclusion the important task which he has set himself.

Dr. Meyer does not avail himself of the usual mode of illustration by lithography, but has had all the skeletons photographed from nature, and then reproduced by

[1] "Abbildungen von Vogel-Skeletten herausgehen mit Unterstützung der generaldirection der konigl, Sammlungen für Kunst und Wissenschaft in Dresden." Von Dr. A. B. Meyer. Parts 1 to 5, pp. 1 to 40, Plates 1 to 50. (Dresden: Published by the Author, 1879-1883.)

phototype. This process does not fade as a photograph is liable to do, but has the consistency of print with the appearance of a steel engraving. By an ingenious method adopted by the author only one side of the bird's skeleton is given in the plate, and thus the confusion which is often seen in osteological illustrations from the appearance of the opposite side of the skeleton in the picture is obviated. The plates, which have been executed in Dresden at Mr. Wilhelm Hoffmann's Art Institute, deserve great credit for their execution. The letterpress which accompanies the figures gives the distinguishing characters of the skeletons with their principal measurements.

It is proposed to issue at least two parts in the course of every year, each part to contain ten plates. Out of the number hitherto published we find illustrations of seventeen Parrots belonging to fourteen genera, amongst them being the rare *Dasyptilus pesqueti* from New Guinea, the smallest known Parrot, *Nasiterna pygmæa*, as well as the largest one, *Microglossus aterrimus*, both of which are from New Guinea, *Nestor meridionalis* and *Stringops habroptilus* from New Zealand, besides illustrations of members of the following genera:—*Eclectus*, *Cacatua*, *Cyclopsitta*, *Loriculus*, *Trichoglossus*, *Charmosyna*, *Brotogerys*, *Tanygnathus*, and *Eos*. Of Birds of Paradise illustrations are given of *Cicinnurus regius*, *Paradisea minor*, *Manucodia chalybeata* with its twisted windpipe, along with those of its allies. Other Birds of Paradise are promised by Dr. Meyer. Among the Pigeons are figured species of *Carpophaga*, *Otidiphaps*, *Œdirhinus* and *Ptilopus*, side by side with skeletons and skulls of some of the domestic races. Of Kingfishers figures of the skeletons of the genera *Cittura*, *Tanysiptera*, and *Sauromarptis* are furnished, and among others we find illustrations of such interesting genera as the following:—*Pelenopides*, *Meropogon*, *Collocalia*, *Heteralocha*, *Rallina*, *Scissirostrum*, *Streptocitta*, *Oriolus*, *Dicrurus*, *Lepidogrammus*, &c.

We must draw the special attention of our readers to the skeleton of a species of *Notornis* from New Zealand, which Dr. Meyer has figured in Plates 34 to 37. This skeleton was procured along with the skin of the bird in South Island, N.Z., in the year 1879, and has found its way to the Dresden Museum. Complete figures of the osteology of this interesting genus are here given for the first time. Our national collection contains two skins of *Notornis*, but no skeleton, only some fossil remains from the North Island having been described and figured in the year 1848 by Prof. Owen. From a comparison of the latter with the skeleton now in the Dresden Museum, Dr. Meyer has been induced to consider that the North Island species is distinct from that inhabiting the South Island, and as the name of *Notornis mantelli* was given by Owen to the former bird, the specimen in the British Museum which came from the South Island must bear the name of *Notornis hochstetteri*, as Dr. Meyer proposes to attach to it the name of the well-known New Zealand explorer, Prof. von Hochstetter of Vienna.

A comparison is instituted by Dr. Meyer between the skeletons of different species of *Porphyrio* and *Ocydromus*. Together with the skeleton of the Jungle-fowl (*Gallus bankiva*), which Dr. Meyer himself brought from Sangi Island, north of Celebes, and different species of grouse (amongst them that of *Tetrao medius*), we find representations of the skeletons of several domesticated races of fowls. The importance of the characters presented by the differences of the crania and other portions of the skeletons of domestic fowls and pigeons was long ago proved by Mr. Darwin, and as there were only certain portions of the skeletons figured by him, the material which Dr. Meyer has collected with great care offers to the student a better opportunity of going deeply into this subject.

R. B. S.

THE "POTÉTOMÈTRE," AN INSTRUMENT FOR MEASURING THE TRANSPIRATION OF WATER BY PLANTS

IN view of the interest now attaching to recent advances in vegetable physiology, it seems not unlikely that a description of the instrument bearing the above name, lately published by Moll (*Archives Néerlandaises*, t. xviii.), will serve a useful purpose.[1] The apparatus was designed to do away with certain sources of error in Sachs's older form of the instrument, described in his "Experimental-Physiologie"—errors chiefly due to the continual alteration of pressure during the progress of the experiment.

As shown in the diagram, the "potétomètre" consists essentially of a glass tube, *a d*, open at both ends, and blown out into a bulb near the lower end; an aperture also

Fig. 2

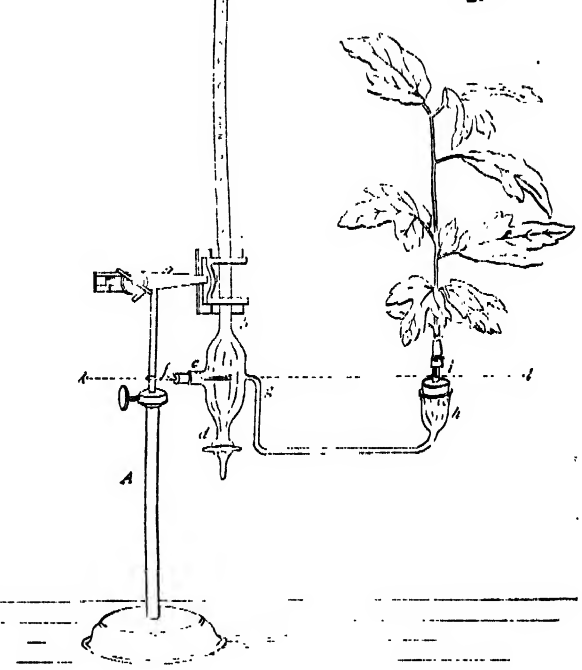

Fig. 1

exists on either side of the bulb at or about its equator. The two ends of the main tube are governed by the stopcocks *a* and *d*, and the greater length of the tube is graduated. A perforated caoutchouc stopper is fitted into one aperture of the bulb *e*, and a tube, *g h*, fits hermetically to the other. This latter tube is dilated into a cup at *h* to receive the caoutchouc stopper, into which the end of the shoot to be experimented upon is properly fixed.

The fixing of the shoot is effected by caoutchouc and wire or silk, as shown at *i*, and must be performed so that the clean-cut end of the shoot is exactly at the level of a tube passing through the perforated stopper, *e*, of the bulb; this is easily managed, and is provided for by the bending of the tube *g h*. The tube *f*, passing horizontally through the caoutchouc stopper *e*, is intended to admit bubbles of air, and so equalise the pressure and at the same time afford a means of measuring the rapidity of the absorption of water by the transpiring shoot. This tube

[1] Especially also with reference to Mr. F. Darwin's description of his own ingenious instrument (see NATURE, May 8, p. 7).

(see Fig. 2, *f*) is a short piece of capillary glass tubing, to which is fixed a thin sheath of copper, *b'*, which slides on it, and supports a small plate of polished copper, *a'*, in such a manner that the latter can be held vertically at a small distance from the inner opening of the tube, and so regulate the size of the bubble of air to be directed upwards into the graduated tube *a b*.

The apparatus is filled by placing the lower end of the main tube under water, closing the tubes *f* and *i* (with caoutchouc tubing and clips), and opening the stopcocks *a* and *d*. Water is then sucked in from *a*, and the whole apparatus carefully filled. The cocks are then turned, and the cut end of the shoot fixed into *i*, as stated: care must be taken that no air remains under the cut end at *i*, and the end of the shoot must be at the level *k l*. This done, the tube *f* may then be opened.

The leaves of the shoot transpire water, which is replaced through the stem at the cut end in *i* from the water in the apparatus. A bubble of air passes through the tube *f*, and at once ascends into the graduated tube *a c*. The descent of the water-level in this tube—which may conveniently be graduated to measure cubic millimetres—enables the experimenter at once to read off the amount of water employed in a given time.

It is not necessary to dwell on obvious modifications of these essentials, nor to speak of the slight difficulties of manipulation (especially with the tube *f*). Of course the apparatus might be mounted in several ways; and excellent results for demonstration in class could be obtained by arranging the whole on one of the pans of a sensitive balance. H. MARSHALL WARD

Botanical Laboratory, Owens College

AURORAL RESEARCHES IN ICELAND

In my last communication to NATURE on the aurora borealis in Iceland (vol. xxix. p. 537), I mentioned that the unusually adverse state of the weather had frustrated my plan of erecting one of the "utströmnings" apparatus invented by Prof. Lemström for the production of the artificial aurora borealis (see NATURE, vol. xxvii. p. 389) on Mount Esja, 2500 feet in height, and about two geographical miles north-east from Reykjavik.

The greatest part of February passed too without showing any improvement, and the prospects of getting the apparatus in working order on the mountain whilst the Arctic night still reigned became smaller and smaller. Although I regretted this, the study of the aurora which I had observed during the winter had, as indicated in my last communication, gradually convinced me that such an apparatus, even at a great height above the level of the earth, would, at all events in this part of Iceland, give but a negative result.

In spite of the favourable position of the island, the electrical forces, for which the aurora borealis is a visible indicator, appear to possess exceedingly little energy and intensity here, which has particularly been the case during the past few months. In consequence I came to the conclusion that should even all my arrangements be carried out to perfection there was little prospect of producing the "artificial" aurora borealis here.

On February 22, however, a change in the weather set in, and we had a few lovely days with a clear sky, no wind, and a pleasant temperature. Now, if ever, the time had come for realising my plan; and as the weather held for three entire days I fixed the departure for noon of the 25th.

I was fortunate enough to be able to make the journey in pleasant company, two of the burghers of the town and two Englishmen engaged at some sulphur mines in the vicinity volunteering to accompany me to the top of the mountain. We started at about 10 a.m. in a large sailing boat, with the poles, wires, and the rest of the apparatus.

In about three hours we landed at the foot of Esja, and took up our quarters in the farm Mogilsau, from whence I despatched the crew in every direction to call up all able-bodied men to assist in bringing the materials up to the top. Already the same afternoon I had ten of the poles carried up to a height of about 1500 feet.

The next morning broke clear and fine, promising a day as fine as the previous one. I had then sixteen men at my disposal. They began work at 6 a.m., carrying the heavy things up the mountain, and at 9 the last were taken out of the boat, and we all followed upwards.

We ascended from the southern side of the mountain about two miles in length. Only now and then we found snow, otherwise the ground consisted of sand and gravel mixed with boulders. The incline is not very great at first, but at times hills and ridges are encountered which tax the muscles and the lungs severely enough. However, the first 2000 feet of the road were not difficult or dangerous; in fact the only part which could be called so were the last 500 to 600 feet. Here the mountain rises abruptly (Esja is formed in terraces), and was covered with a thin layer of snow having a dangerous ice-coating. It was impossible to proceed here without first having hewn steps in the ice.

At 11.20 we mounted the crest of Esja. The mountain stretched snowy-white to all sides as level as a floor. It brought to my mind my ascent of the North Cape last summer. There was a slight breeze blowing which made the air feel chilly. The thermometer showed in the sun at 1 p.m. − 1·2°, at 2 − 0·2°, and at 3, in the shade, − 3·2° Cels.

Every hand now became busy with erecting the apparatus. The layer of snow on the surface of the mountain was not thick enough to support the poles, and as the ground was frozen hard, they were—thirty-one in number—raised in cairns of large boulders, of which there were great quantities on the edge of the plateau. The poles being raised, the copper wires, along which there were fixed more than a thousand fine points, were suspended over the insulators on their tops. The wires were 850 feet in length, and the poles were erected in such a manner that square spiral slings were formed, having a distance of 6 feet from each other. The total surface area of the "utströmnings" apparatus is therefore 4100 square feet.

The work of erecting the apparatus occupied about four hours, and from the four barometrical observations I had an opportunity of making during the time—in conjunction with those which were, at my request, simultaneously, and with a similar instrument, effected at Reykjavik—I have fixed the height at which the apparatus stands at 2616 feet.

At 3.30 the descent began. The first part of this was far more risky than the ascent, as the steps cut became worn down and new ones had to be made. Simultaneously a very strong copper wire, carefully insulated by layers of canvas and indiarubber—the insulation being 6 mm. in diameter—was brought down the mountain by the shortest road, as far as it reached.

The next morning welcomed us with wind and heavy clouds, with a rapidly-falling barometer. The remaining poles were now brought up the mountain, and the bare telegraph wire, 3200 feet in length, carried to the spot where the insulated conductor ended. Both wires were connected in the most careful and exact manner, and the bare wire laid down as an ordinary telegraph wire on poles with insulators as far as it went. I had expected from its great length that it would reach down to the foot of the mountain, but it did not; it only reached to a height of 714 feet. When the wires in increasing rain and wind were laid out, I connected the end with two zinc disks one of which was placed in a small waterfall with heavy stones on it, and the other buried in the earth. When, finally, I had by means of a telephone and a gal-

vanic element, conclusively ascertained that the conductor was in perfect working order right up to the top of the mountain, we began the descent and the return journey as rapidly as possible. We had no other choice, as the storm and rain which every moment increased precluded every possibility of doing more at that time. I had, however, some consolation in what already was done, my apparatus standing 1900 feet above the disks.

I left all the instruments to be used in connection with the experiments at Mogilsau in hopes that the weather would soon improve and allow me to return. The journey to Reykjavik was performed in a downpour of rain and a great storm.

As I had anticipated, the "utströmnings" apparatus has up to the present shown no signs of life whatever. I can see it plainly with a good telescope from my residence, and thus ascertain that it is in perfect order. In addition, I have just received a message from Mogilsau, informing me that the lower part is in perfect order too. Still during the few favourable nights we have as yet experienced not the slightest luminosity has appeared above the point in question.

If this be a negative result, it is a result, nevertheless, of considerable scientific interest.

The aurora borealis here has during the last few months been far more distinct in its appearance than during the first half of the winter. There is certainly, when the sky is sufficiently free from clouds, here and there a faint indication that the phenomenon does still exist, but such signs of life are very weak and limited.

I have at present no knowledge whether the aurora borealis has displayed less activity in other quarters of the globe during the winter than is generally the case, as letters take a long time from and to this island, but the Reykjavik people contend that the phenomenon displays usually far more energy and intensity than has been the case this winter. I am at present inquiring in various parts of the island whether the absence of the aurora borealis this winter has been noticed as generally remarkable, or its appearance is the usual one in Iceland.

In my last communication to NATURE I intended to have mentioned that I was curious to know what the effect would be of a sufficiently strong aurora covering the moon's disk. During the winter I have had several opportunities of observing auroræ projecting over the disk of the moon when full, but nothing more unusual is seen than the light of the aurora borealis disappearing within a radius of 5° to 10° around the moon. But in the appearance of the latter there is no difference.

Reykjavik, March SOPHUS TROMHOLT

A CARNIVOROUS PLANT PREYING ON VERTEBRATA

AN interesting discovery has been made during the last week by Mr. G. E. Simms, son of a well-known tradesman of Oxford. It is that the bladder-traps of *Utricularia vulgaris* are capable of catching newly-hatched fish and killing them. Mr. Simms brought to me for examination a specimen of Utricularia in a glass vessel, in which were numerous young roach newly hatched from a mass of spawn lying at the bottom. Numbers of these young fish were seen dead, held fast in the jaws of the bladder-traps of the plant. I had never seen Utricularia before, and am indebted to my colleague Prof. Burdon Sanderson for the identification of the plant and a reference to Cohn's researches on it. Mr. Simms supplied me with a fresh specimen of Utricularia in a vessel with fresh young fish and spawn, and in about six hours more than a dozen of the fish were found entrapped. Most are caught by the head, and when this is the case the head is usually pushed as far into the bladder as possible till the snout touches its hinder wall. The two dark black eyes of the fish then show out conspicuously through the wall of the bladder. Rarely a specimen is seen caught only by the tip of the snout. By no means a few of the fish are, however, captured by the tail, which is swallowed, so to speak, to a greater or less distance, and I have one specimen in which the fish is caught by the yelk sac. Three or four instances were observed in which a fish had its head swallowed by one bladder-trap, and its tail by another adjacent one, the body of the fish forming a connecting bar between the two bladders.

I have not been able to see a fish in the actual process of being trapped, nor to find one recently caught, and showing by motion of the fore part of its body signs of life. All those trapped were found already dead, but I have had no opportunity of prolonged observation, and it will be remembered that Mr. Darwin, in his account of the trapping of Crustacea, worms, &c., by Utricularia, states that he was not able to observe the actual occurrence of the trapping of an animal, although Mrs. Treat of New Jersey often did so. I think it probable that the fact described by Mr. Darwin, and which is easily verified, that the longer of the two pairs of projections composing the quadrifid processes by which the bladders of Utricularia are lined "project obliquely inwards and towards the posterior end of the bladder," has something to do with mechanism by which the small fish become so deeply swallowed so to speak. The oblique processes, set all towards the hinder end of the bladder, look as if they must act together with the spring valves of the mouth of the bladder in utilising each fresh struggle of the captive for the purpose of pushing it further and further inwards. On cutting open longitudinally some of the bladders containing the heads and foreparts of the bodies of fish, and examining their contents, I found the tissues of the fish in a more or less slimy deliquescent condition, no doubt from decomposition, for Mr. Darwin failed to detect any digestive process in Utricularia. The quadrifid processes were bathed in the slimy semi-fluid animal substance, and the processes themselves appeared to contain abundance of fine granular matter, possibly the result of absorption, but the large quantity of surrounding animal matter present rendered the observation uncertain. The usual swarms of Infusoria were present in the decomposing matter.

Specimens of the Utricularia with the little fish fast in the bladder-trap, and their heads or tails hanging out, can be well preserved in spirits, and show the conditions well, notwithstanding that the plant becomes colourless, and there is no longer the marked contrast between the glistening white dead fish and the green bladders, which in the fresh condition renders the combination of the trap and prey conspicuous.

Mr. Simms, by whose permission I write this, intends shortly to publish an account of his observations himself. I have advised him to endeavour to prepare spirit specimens of Utricularia plants with numerous trapped fish *in situ* for sale to those interested in the matter who may care to apply for them. His address is 37, Broad Street, Oxford. H. N. MOSELEY

NOTES

M. PASTEUR read to the Academy of Sciences on Monday an account of his experiments on rabies. He maintains that he has twenty dogs which he has rendered insusceptible to the disease, and which, with twenty ordinary dogs, he is prepared to have bitten by a number of dogs in a rabid state. A Commission has been appointed by the French Government to test M. Pasteur's conclusions, the immense importance of which, if established, must be evident to every one. Eminent physiologists maintain, however, that M. Pasteur is far from having proved his position, and that it would be rash to give any positive opinion upon the subject until the experiment which he suggests has been made. We await the full report of M. Pasteur's paper before saying more upon

it. The following are the members of the Government Commission:—Dr. Beclard, the Dean of the Paris Faculty; M. Paul Bert, Professor of General Physiology at the Faculty of Sciences; M. Bouley, Professor of Comparative Pathology at the Museum of Natural History; Dr. Villemin, Professor of Clinical Surgery at the Military Pharmacy; Dr. Vulpian, Professor of Comparative and Experimental Pathology at the Paris Faculty of Medicine; and M. Tisserand, Director of the Agricultural Department.

PROF. HUXLEY has undertaken to be President of the Marine Biological Association. It is stated that Plymouth will probably be selected as the site of the first laboratory and experimental station erected by the Association. The Duke of Argyll, the Duke of Sutherland, and Dr. Gwyn Jeffreys, F.R.S., have given their names as vice-presidents. Mr. Chamberlain has joined the Association, and subscribed twenty guineas towards building the sea-coast laboratory. Mr. Thomasson, M.P. for Bolton, has subscribed 100*l*.

WE understand that the Scottish Fishery Board have obtained sufficient funds to enable Prof. McIntosh to carry on a number of important preliminary inquiries at St. Andrew's as to the possibility of increasing by artificial means the supply of flat-fish, and also as to the spawning habits and life-history of food fishes in general. This work is in the meantime being carried on in a temporary building which for some time served as a hospital. It is hoped, however, that when the importance of the work and the many advantages which St. Andrew's offers for a marine station are recognised, that both in the interest of science and by way of developing further the great fishing industry, a well-equipped laboratory and hatching station will be provided. Dr. McIntosh has already succeeded in hatching from artificially fertilised eggs the flounder, whiting, haddock, and cod, and in determining the nature of the eggs of the gurnard and other fish. Prof. Hubrecht of Utrecht is expected to work at the St. Andrew's Marine Station during the autumn.

THE Davis Lectures upon zoological subjects will be given in the lecture-room in the Zoological Society's Gardens, Regent's Park, on Thursdays, at 5 p.m., commencing June 5, as follows:—June 5, Man, zoologically considered, by Prof. Flower, LL.D., F.R.S.; June 12, Hands and feet, by Prof. Mivart, F.R.S.; June 19, Instinct, by G. J. Romanes, LL.D., F.R.S.; June 26, Hedgehogs, moles, and shrews, by Prof. Parker, F.R.S.; July 3, Dogs, ancient and modern, by J. E. Harting, F.L.S.; July 10, Birds' nests, by Henry Seebohm, F.L.S.; July 17, Reptiles, by P. L. Sclater, F.R.S.

THE Municipal Council of Paris has, at the instigation of the Société d'Anthropologie, given its sanction to the projected erection of a monument to Paul Broca. The spot chosen is a triangular plot of ground on the Boulevard Saint-Germain, immediately opposite the entrance gate of the new wing of the École de Médecine. A Commission has been appointed to decide upon the terms and conditions to be observed by those who desire to enter into the competition shortly to be opened for the honour of executing the work.

THE eighth meeting of the French National Congress of Geography will open on August 8 at Toulouse, where the local Geographical Society is organising an international exhibition, to be held from June 1 to August 15.

IN reference to his "Prize Records of Family Faculties" Mr. F. Galton writes to the *Times*:—"Permit me, as the last day for sending in the records has just gone by, to send you a brief estimate of the value of the response to my offer, so far as a very hasty inspection warrants. This value has far exceeded my expectations. I have received very little trash, and upwards of 150 good records of different families. Many of these are admirably drawn up; concise, full of information, and offering numerous opportunities of verification. As each of these returns refers to fourteen direct ancestors of the children of the family, and to many of the brothers and sisters of each of them, the mass of anthropological material may be inferred. It certainly refers to more than 5000 persons, and as the data are all entered in my bound tabular forms, the records form a long row of thin quarto volumes, severally labelled, and easily accessible. It is a unique anthropological collection. The writers are chiefly persons of the upper and middle classes of society; they are male and female in nearly equal proportions, and the two sexes write equally well, so far as I can thus far judge. The letters that accompanied the records are full and friendly, expressing a trust that I can assure them will not be misplaced of my treating the information as strictly confidential. In many cases they express the great interest that the inquiry into their own family history has been to them. Permit me to add that I do not think it possible to determine the prizes in much less than two months, and that besides publishing the awards I propose to send a copy of them to the private address of every substantial competitor."

No. 16 of the Bibliographical Contributions of the Library of Harvard University consists of a classified index to the maps in *Petermann's Geographische Mittheilungen*, 1855-81, by Mr. Richard Bliss. The index consists of 1340 entries, and has evidently been made with the greatest care. Mr. Bliss has done a work of great utility.

IN two papers entitled "Le Ceneri dei Volcani di Giava supposta Causa dei Bagliori Crepuscolari," and "L'Isola di Giava ed i Crepuscoli del Novembre e Decembre 1883," recently published at Vicenza, Alvise G. Mocenigo discusses the various theories put forward to explain the late remarkable crepuscular lights that have been observed in every part of the world. He thinks the phenomena should probably be attributed to extra-telluric, interplanetary, or cosmic conditions naturally recurring only at long intervals, and which may possibly have never before arisen since the appearance of man on the earth.

THE Mitchell Library at Glasgow still labours under that most satisfactory of difficulties—want of room in which to carry on the amount of work it could otherwise do. Seldom has this want been more heavily felt than here, where not one-tenth of its founder's bequest of 70,000*l*. has yet been expended, while an additional legacy of 11,500*l*., exceeding the entire expenditure in books hitherto, lies unused for sheer want of space to make available any such treasures as it would secure. The moderate increase of between 4 and 5 per cent. in its total issues of books is reasonably attributed to this limitation. Glasgow has not yet adopted the Free Libraries Act, but the Corporation has placed the complete publications of the Patent Office at another library founded by Walter Stirling, a merchant of that city, in 1791. As a reference library this also is free, and a recent reorganisation has reduced the subscription to its circulating department to 10*s*. 6*d*. a year, or half that where four members of a firm enter together. This arrangement has led to a large increase of readers at both branches of this library, but that has not interfered with the use made of the Mitchell Library, and it is satisfactory to find in the Report of the latter a notice in large type referring all persons who wish to take books home to the moderate terms of the sister establishment. Still the subscribers to the latter form but a small fraction of the numbers who would be sure to avail themselves of rate-supported libraries in a great town like Glasgow, and the Mitchell Report strongly and wisely urges the adoption of the Act.

VISITORS to Canada during the forthcoming meeting of the British Association will find many useful hints and considerable practical guidance in Mr. T. Greenwood's "Tour in the United States and Canada." Mr. Greenwood went out and back in six weeks, and evidently made good use of his time.

THE demonstration by Dr. Herbert Carpenter of some points in the mi[illegible] anatomy of Crinoids at the last meeting of the

Royal Microscopical Society was of great interest, and gave promise that his forthcoming *Challenger* Report will be of high importance as a contribution to the morphology of these Echinoderms. His exhibition of microscopic preparations of the system of cords which he and his father assert to be of a nervous nature was supplemented by an interesting account by Dr. Carpenter, C.B., of the observations and experiments which had led to the conviction as to their nervous nature, which is gradually being accepted by other investigators.

M. MASCART, Professor at the College of France, will give a discourse at the Royal Institution on Friday evening, May 30, the subject being "Sur les Couleurs."

WE regret to learn of the death of Mr. Henry Baden Pritchard, whose name has been so long connected with the *Photographic News*, and with the photographic world in general.

A STRONG earthquake shock causing some damage was felt last week at Panderma and Erdek in the province of Broussa, Asia Minor. Two slight shocks, unattended by any damage, have occurred at Balikesri in the same province.

AT a meeting of the Governors of North Wales University, held last week at Bangor, Mr. Henry Rudolf Reichel, M.A., Fellow of All Souls College, Oxford, was elected Principal of the College.

THAT the railway should be the means of enriching the flora of a district seems strange. This has, however, been shown to be the case in Arbrå parish, in the province of Helsingland, Sweden. Thus, since the extension of the Great Northern main line into this province in 1878, no less than seven new species of plants have immigrated along the line. They are *Galium mollugo*, *Plantago lanceolata*, *Euphorbia helioscopia*, *Dactylis glomerata*, *Bunias orientalis*, *Avena fatua*, and an American importation, *Rudbeckia hirta* (L.). That these must owe their introduction to the railway is clearly demonstrated by the fact that in spite of the closest scrutiny these plants have never before been found in this district, and that they are even now confined to the railway embankment and its immediate vicinity. The four first-named have, in all probability, only come from the parishes south of Arbrå, but the *Bunias orientalis* and *Avena fatua* have no doubt travelled along the line all the way from the province of Gestrikland, to whose flora they belong. The last-named, *Rudbeckia hirta*, which hails from the eastern part of the United States, seems to follow in the track of the navvy in the whole of Northern Sweden. In the summer of 1880 it was seen some ten miles south of Bollnäs station; in 1882 it appeared for the first time at Arbrå, about twenty miles further up the railway line; and last year it had travelled as far as Torps parish, in the province of Medelpad, *i.e.* a distance in four years of about one degree.

A CORRESPONDENT writes in reference to Prof. McKenny Hughes' article on earthworms, that the worst consequence of the sea going over the walls in the Somerset low grounds is that it kills the worms, thousands of which come to the surface and die in agony, and the farmers are very sensible of the evil done to the land for a long time afterwards.

MESSRS. CROSBY LOCKWOOD AND CO. inform us that they will shortly publish "A Treatise on Earthy and other Minerals and Mining," by D. C. Davies, F.G.S. The work, which is uniform with and forms a companion volume to the same author's "Treatise on Metalliferous Minerals and Mining," will be fully illustrated. The same publishers announce a work on an entirely new subject, viz. "Stone-working Machinery, and the Rapid and Economical Conversion of Stone, with Hints on the Arrangement and Management of Stone-Works," by M. Powis Bale, M.Inst.M.E., A.M.Inst.C.E. Messrs. Crosby Lockwood and Co. also announce "The Blowpipe in Chemistry, Mineralogy, and Geology," by Lieut.-Col. Ross.

THE additions to the Zoological Society's Gardens during the past week include a Hodgson's Partridge (*Perdix hodgsoniæ*), presented by Mr. W. Jamrach; a Bonnet Monkey (*Macacus radiatus*), presented by Mr. A. King; two Japanese Pheasants (*Phasianus versicolor*), two Egyptian Geese (*Chenalopex ægyptiaca*), a White American Crane (*Grus americana*), thirteen Green Lizards (*Lacerta viridis*), purchased; two Common Vipers, presented by Mr. W. H. B. Pain; a Common Partridge (*Perdix cinerea*), presented by Mr. R. Steele; a Banded Ichneumon (*Herpestes fasciatus*), presented by Master Adams; twelve Variegated Sheldrakes (*Tadorna variegata*), four Soft-billed Ducks (*Hymenolæmus malacorhynchus*), a Bernicle Goose (*Bernicla leucopsis*), an Argentine Tortoise (*Testudo argentina*), presented by Mr. Wm. Petty.

OUR ASTRONOMICAL COLUMN

A NEW COMET OF SHORT PERIOD.—M. Schulhof of Paris has lately ascertained that the observations of the third comet of 1858 (a very limited number) are closely represented by an elliptical orbit with a period of about six years and a half. The comet in question was discovered by Mr. H. P. Tuttle at the Observatory of Cambridge, Mass., on the evening of May 2; it was observed there until May 12, and likewise at Ann Arbor by the late Prof. Watson from May 9 until June 1. Eight observations in all are available for the calculation of the orbit, and upon these M. Schulhof bases four positions, from which he deduces the following elements:—

Perihelion passage, 1858 May 2·96719 G.M.T.

	°	′	″
Longitude of perihelion	200	46	27·1
,, ascending node	175	4	8·5
Inclination	19	30	2·0
Angle of eccentricity	41	21	5·2
Mean daily sidereal motion			536″·881

From these elements we find—

Eccentricity	0·660676	Perihelion distance	1·1950
Semi-axis major ...	3·5217	Revolution ...	6·609 years
,, minor ...	2·6436		

M. Schulhof finds the limits for the mean daily motion 612″ and 470″ corresponding to periods of 5·80 and 7·55 years.

With such elements the comet must approach very near to the orbit of Jupiter, as is the case with nearly all the comets of the short-period group: and with the most probable period (6·6 years) would come into close proximity to the planet in 1879 and 1880. It unfortunately happens that an endeavour to identify this comet with any one of the imperfectly observed comets of past times, or with missing nebulous objects, has so far been fruitless, and hence much uncertainty remains as to the true length of the revolution, but M. Schulhof has prepared sweeping-ephemerides, of which a part is printed in No. 2590 of the *Astronomische Nachrichten*: it contains the sweeping-line for every fourth degree of the sun's true longitude from 40° to 104°. At the time of discovery in 1858 the comet was a very faint object in the comet-seeker, and continued faint during the month that it was observed. To this circumstance and unfavourable weather is attributed its not having been seen at Washington: it was not observed in Europe. Parabolic elements were computed by Profs. Hall and Watson, but no suspicion of periodicity could have arisen from the results of their calculations beyond what comparatively small inclination and direct motion might have suggested; indeed we believe it is somewhere upon record that Prof. Hall considered the tendency was rather towards a hyperbolic orbit. M. Schulhof's merit in drawing the attention of astronomers to the real nature of the comet's path is so much the greater.

Could reliance be placed upon the period given by the few observations in our possession as the most probable one, a return to perihelion might be expected in October next, but as already remarked such period would have brought the comet into close proximity to the planet Jupiter in 1879-80, and the next perihelion passage might be considerably affected thereby. Further, it is to be remarked that with perihelion passage in the middle

of October there would be little or no chance of recovering the comet.

The comet's heliocentric equatorial-coordinates at perihelion are—

x ... $-1\cdot1148$ y ... $-0\cdot4305$ z ... $+0\cdot0018$.

If we combine these with the sun's coordinates, X, Y, Z, in the *Nautical Almanac*, we readily obtain an idea as to the chances of finding the comet, according to different assumed dates of arrival at perihelion. The most advantageous conditions are presented when this falls about the middle of April. If we assume April 11, the R.A. is found to be 208°, N.P.D. 54°, and the intensity of light 11·05, which is four times greater than on the date of the comet's discovery by Tuttle in 1858. As it was then extremely faint, its rediscovery may be a matter of difficulty. We have already one "Tuttle's comet," of short period, and it may perhaps occur to astronomers that the third of 1858 will be aptly named *Schulhof's comet*.

CHEMICAL NOTES

POTILITZIN has recently (*Ber.*, xvii. 276) made some interesting observations on the hydration and dehydration of cobalt chloride. He shows that, besides the already known hydrate $CoCl_2 . 6H_2O$, there exist two hydrates, $CoCl_2 . 2H_2O$ and $CoCl_2 . H_2O$, the former being rose-red in colour, and the latter dark violet. When the dehydrated salt is heated to about 100°, it parts with water, which is again absorbed on cooling. When an aqueous solution of the ordinary hexhydrated salt is heated, or is mixed with a dehydrating agent, the colour changes from pink to blue or dark violet. Potilitzin shows that this change, which he proves to be due to partial decomposition of the hexhydrated salt, may be brought about without raising temperature by the capillary action of unsized paper or a porous plate of stucco.

TOLLENS has made experiments on the sugar-like substance obtained by the action of alkalies on an aqueous solution of formaldehyde. He oxidises methylic alcohol by air in presence of platinum foil at 54°-55°, and distils; he then treats the crude distillate with baryta water, and so obtains a yellowish precipitate, which, when freed from barium, yields an amorphous syrup that reduces Fehling's solution, and gives results on analysis approximating to the formula $C_6H_{10}O_5$. This syrup is optically inactive, and does not undergo fermentation; on treatment with sulphuric acid, it gives formic and lactic acids (*Landw. Versuchs-Stat.*, xxix. 355).

KANNONIKOW (*Ber.*, xvii. p. 157, *abstracts*) attempts to measure the refraction-equivalents of various metals by deducting the refraction-equivalents of salts of these metals with organic acids (determined with aqueous solutions of the salts) from the refraction-equivalents of the acids themselves. So far as his results go, they appear to indicate that the refraction-equivalents vary periodically with variations in the atomic weights of the metals.

MM. NILSON AND PETTERSON have prepared pure beryllium chloride by heating the metal in perfectly dry hydrochloric acid gas, and have determined the density of the vapour of this compound. Beryllium chloride can be volatilised without decomposition in an atmosphere of dry nitrogen or carbon dioxide, provided every trace of air is excluded. The density of the gaseous compound for the temperature-interval 686°-812° agrees with that calculated from the formula $BeCl_2$ (Be = 9·1). The question as to the value to be assigned to the atomic weight of beryllium, which has been so much discussed of late, appears to be now finally settled in favour of the number deduced by applying the periodic law to the study of the properties of this metal and its compounds (*Ber.* xvii. 987).

CONTINUING the researches of Krämers, Prof. Mendeléeff has shown at a recent meeting of the Russian Chemical Society (*Journal* of the Society, vol. xvi. fasc. 2) that the densities of solutions of salts increase together with the increase of their molecular weights. Thus if we take the series of salts HCl, LiCl, NaCl, KCl, . . . $BaCl_2$, $SnCl_4$, $HgCl_2$, and Fe_2Cl_6, the molecular weights of which are respectively 36·5, 42·5, 58·5, 74·5, . . . 208, 259, 271, and 325, the densities of their solutions in 100 parts of water, at 15° to 20°, are: 1·010, 1·014, 1·023, 1·025, . . . 1·098, 1·106, 1·128 (calculated), and 1·134. The densities increase as the molecular weights increase; but if we take, instead of the molecular weights, the weights of their equivalents, or those of the equivalents of metals, the regularity of increase disappears. Prof. Mendeléeff adds that the above is true, not only with regard to chlorides, but also with regard to the salts of bromine and iodine, and many others. Reserving to himself further to pursue his researches in this way, Prof. Mendeléeff points out the following relation:—If the molecular weight of the dissolved body be M, and the solution be represented by $nM + 100\,H_2O$ (where n represents the number of molecules), the density, D, of the solution may be expressed for many bodies by the following equation:—$\left(\frac{n}{D - D_0}\right)^k = A + Bn$, where D_0 is the density of water, and k is equal to unity, or very near to it. This equation must be considered, however, only as preliminary, ulterior researches promising to give a more general formula. A and B are two constants, which vary with the temperature. Thus, for HCl at 0° (the density of water at 4° being taken = 1), A = 94·5 and B = 1·725; at 20°, A = 102·2, and B = 1·80; at 40° A = 106·2, and B = 1·85; at 60° A = 105·2, and B = 2·05; at 80° A = 100·6, and B = 2·25; and at 100° A = 94·5, and B = 2·55, the coefficient k being in all cases equal to unity.

ON THE NOMENCLATURE, ORIGIN, AND DISTRIBUTION OF DEEP-SEA DEPOSITS[1]

Introduction

THE sea is unquestionably the most powerful dynamic agent on the surface of the globe, and its effects are deeply imprinted on the external crust of our planet; but among the sedimentary deposits which are attributed to its action, and among the effects which it has wrought on the surface features of the earth, the attention of geologists has, till within quite recent times, been principally directed to the phenomena which take place in the immediate vicinity of the land. It is incontestable that the action of the sea along coasts and in shallow water has played the largest part in the formation and accumulation of those marine sediments which, so far as we can observe, form the principal strata of the solid crust of the globe; and it has been from an attentive study of the phenomena which take place along the shores of modern seas that we have been able to reconstruct in some degree the conditions under which the marine deposits of ancient times were laid down.

Attention has been paid only in a very limited degree to deposits of the same order, and, for the greater part, of the same origin, which differ from the sands and gravels of the shores and shallow waters only by a lesser size of the grains, and by the fact that they are laid down at a greater distance from the land and in deeper water. And still less attention has been paid to those true deep-sea deposits which are only known through systematic submarine investigations. One might well ask what deposits are now taking place, or have in past ages taken place, at the bottom of the great oceans at points far removed from land, and in regions where the erosive and transporting action of water has little or no influence. Without denying that the action of the tidal waves can, under certain special conditions, exert an erosive and transporting power at great depths in the ocean, especially on submerged peaks and barriers, it is none the less certain that these are exceptional cases, and that the action of waves is almost exclusively confined to the coasts of emerged land. There are in the Pacific immense stretches of thousands of miles where we do not encounter any land, and in the Atlantic we have similar conditions. What takes place in these vast regions where the waves exercise no mechanical action on any solid object? We are about to answer this question by reference to the facts which an examination of deep-sea sediments has furnished.

A study of the sediments recently collected in the deep sea shows that their nature and mode of formation, as well as their geographical and bathymetrical distribution, permit deductions to be made which have a great and increasing importance from a geological point of view. In making known the composition of these deposits and their distribution, the first outlines of a geological map of the bottom of the ocean will be sketched.

This is not the place to give a detailed history of the various contributions to our knowledge of the terrigenous deposits in deep water near land, or of those true deep-sea deposits far removed from land, which may be said to form the special subject of this communication. From the time of the first expeditions under-

[1] A Paper read before the Royal Society of Edinburgh by John Murray and A. Renard. Communicated by John Murray

taken with a view of ascertaining the depth of the ocean, small quantities of mud have been collected by the sounding lead and briefly described. We may recall in this connection the experiments of Ross and the observations of Hooker and Maury. These investigations, made with more or less imperfect appliances, immediately fixed the attention, without however giving sufficient information on which to establish any general conclusions as to the nature of the deposits or their distribution in the depths of the sea.

When systematic soundings were undertaken with a view of establishing telegraphic communication between Europe and America, the attention of many distinguished men was directed to the importance, in a biological and geological sense, of the specimens of mud brought up from great depths. The observations of Wallich, Huxley, Agassiz, Baily, Pourtalès, Carpenter, Thomson, and many others, while not neglecting mineralogical and chemical composition, deal with this only in a subordinate manner. The small quantities of each specimen at their command, and the limited areas from which they were collected, did not permit the establishment of any general laws as to their composition or geographical and bathymetrical distribution. These early researches, however, directed attention to the geological importance of deep-sea deposits, and prepared the way for the expeditions organised with the special object of a scientific exploration of the great ocean basins.

The expedition of the *Challenger* takes the first rank in these investigations. During that expedition a large amount of material was collected and brought to England for fuller study under the charge of Mr. Murray, who has in several preliminary papers pointed out the composition and varieties of deposits which are now forming over the floor of the great oceans. In order to arrive at results as general as possible, it was resolved to investigate the subject from the biological, mineralogical, and chemical points of view, and M. Renard was associated with Mr. Murray in the work. In addition to the valuable collections and observations made by the *Challenger*, we have had for examination material collected by other British ships, such as the *Porcupine*, *Bulldog*, *Valorous*, *Nassau*, *Swallow*, *Dive*; and, through Prof. Mohn, by the Norwegian North Atlantic Expedition. Again, through the liberality of the United States Coast Survey and Mr. A. Agassiz, the material amassed in the splendid series of soundings taken by the American ships *Tuscarora*, *Blake*, and *Gettysburg*, were placed in our hands. The results at which we have arrived may therefore be said to have been derived from a study of all the important available material.

The work connected with the examination and description of these large collections is not yet completed, but it is sufficiently advanced to permit some general conclusions to be drawn which appear to be of considerable importance. In addition to descriptions and results, we shall briefly state the methods we have adopted in the study. All the details of our research will be given in the Report on the Deep-Sea Deposits in the *Challenger* series, which will be accompanied by charts indicating the distribution, plates showing the principal types of deposits as seen by the microscope, and numerous analyses giving the chemical composition and its relation to the mineralogical composition. The description of each sediment will be accompanied by an enumeration of the organisms dredged with the sample, so as to furnish all the biological and mineralogical information which we possess on deep-sea deposits, and finally, we shall endeavour to establish general conclusions which can only be indicated at present.

Before entering on the subject, we believe it right to point out the difficulties which necessarily accompany such a research as the one now under consideration, difficulties which arise often in part from the small quantity of the substance at our disposal, but also from the very nature of the deposit. Since we have endeavoured to determine, with great exactitude, the composition of the deposit at any given point, we have, whenever possible, taken the sample collected in the sounding-tube. That procured by the trawl or dredge, although usually much larger, is not considered so satisfactory on account of the washing and sorting to which the deposit has been subjected while being hauled through a great depth of water. We have, however, always examined carefully the contents of these instruments, although we do not think the material gives such a just idea of the deposit as the sample collected by the sounding-tube. The material collected by the last-named instrument has been taken as the basis of our investigations, although the small quantity often gives to it an inherent difficulty. It was the small quantity of substance collected by the sounding-tube in early expeditions which prevented the first observers from arriving at any definite results; but when such small samples are supplemented by occasional large hauls from the dredge or trawl, they become much more valuable and indicative of the nature of the deposit as a whole. Not only the scantiness of the material, but the small size of the grains, which in most instances make up deep-sea deposits, render the determinations difficult. In spite of the improvements recently effected in the microscopical examination of minerals, it is impossible to apply all the optical resources of the instrument to the determination of the species of extremely fine, loose, and fractured particles. Again, the examination of these deposits is rendered difficult by the presence of a large quantity of amorphous mineral matter, and of shells, skeletons, and minute particles of organic origin. It is also to be observed that we have not to deal with pure and unaltered mineral fragments, but with particles upon which the chemical action of the sea has wrought great changes, and more or less destroyed their distinctive characters.

What still further complicates these researches is the endeavour to discover the origin of the heterogeneous materials which make up the deposits. These have been subjected to the influence of a great number of agents of some of which our knowledge is to a great extent still in its infancy. We must take into account a large number of agents and processes, such as ocean currents; the distribution of temperature in the water at the surface and at the bottom; the distribution of organisms as dependent on temperature and specific gravity of the water; the influence of aërial currents; the carrying power of rivers; the limit of transport by waves; the eruptions of aërial and submarine volcanoes; the effect of glaciers in transporting mineral particles, and, when melting, influencing the specific gravity of the water, which in turn affects the animal and plant life of the surface. It is necessary to study the chemical reactions which take place in great depths; in short, to call to our aid all the assistance which the physical and biological sciences can furnish. It will thus be understood that the task, like all first attempts in a new field, is one of exceptional difficulty, and demands continued effort to carry it to a successful issue.

In presenting a short *résumé* of our methods, of the nomenclature we have adopted, and of the investigation into the origin of the deposits in the deep sea and deeper parts of the littoral zones, we offer it as a sketch of our research, prepared to modify the arrangements in any way which an intelligent criticism may suggest.

Before proceeding to a description of methods and of the varieties of deposits, with their distribution in modern oceans, we will briefly enumerate the materials which our examination has shown take part in the formation of these deposits, state the origin of these materials, and the agents concerned in their deposition, distribution, and modification.

Materials.—The materials which unite to form the deposits which we have to describe may be divided into two groups, viewed in relation to their origin, viz., mineral and organic.

The mineral particles carried into the ocean have a different form and size, according to the agents which have been concerned in their transport. Generally speaking, their size diminishes with distance from the coast, but here we limit our remarks to the mineralogical character of the particles. We find isolated fragments of rocks and minerals coming from the crystalline and schisto-crystalline series, and from the clastic and sedimentary formations; according to the nature of the nearest coasts they belong to granite, diorite, diabase, porphyry, &c.; crystalline schists, ancient limestones, and the sedimentary rocks of all geological ages, with the minerals which come from their disintegraration, such as quartz, monoclinic and triclinic feldspars, hornblende, augite, rhombic pyroxene, olivine, muscovite, biotite, titanic and magnetic iron, tourmaline, garnet, epidote, and other secondary minerals. The trituration and decomposition of these rocks and minerals give rise to materials more or less amorphous and without distinctive characters, but the origin of which is indicated by association with the rocks and minerals just mentioned.

Although the debris of continental land to which we have just referred plays the most important *rôle* in the immediate vicinity of shores, yet our researches show beyond doubt that when we pass out towards the central parts of the great ocean basins, the debris of continental rocks gradually disappears from the deposits, and its place is taken by materials derived from modern volcanic rocks, such as basalts, trachytes, augite-andesites, and vitreous

varieties of these lithological families, for instance, pumice, and loose, incoherent, volcanic particles of recent eruptions, with their characteristic minerals. All these mineral substances being usually extremely fine or areolar in structure, are easily attacked by the sea water at the place where they are deposited. This chemical action brings about an alteration of the minerals and vitreous fragments, which soon passes into complete decomposition, and in special circumstances gives rise to the formation of secondary products. In some places the bottom of the sea is covered with deposits due to this chemical action, principal among which is clayey matter, associated with which there are often concretions composed of manganese and iron. In other regions the reactions which result in the formation of argillaceous matter from volcanic products give rise also to the formation of zeolites.

Among other products arising from chemical action, probably combined with the activity of organic matter, may be mentioned the formation of glauconite and phosphatic nodules, with, in some rare and doubtful examples, the deposition of silica. The decomposition of the tissues, shells, and skeletons of organisms adds small quantities of iron, fluorine, and phosphoric acid to the inorganic constituents of the deep-sea deposits.

Finally, we must mention extra-terrestrial substances in the form of cosmic dust.

We now pass to the consideration of the *rôle* played by organisms in the formation of marine deposits. Organisms living at the surface of the ocean, along the coasts, and at the bottom of the sea are continually extracting the lime, magnesia, and silica held in solution in sea water. The shells and skeletons of these, after the death of the animals and plants, accumulate at the bottom and give rise to calcareous and siliceous deposits. The calcareous deposits are made up of the remains of coccospheres, rhabdospheres, pelagic and deep-sea Foraminifera, pelagic and deep-sea Mollusks, Corals, Alcyonarians, Polyzoa, Echinoderms, Annelids, Fish, and other organisms. The siliceous deposits are formed principally of frustules of Diatoms, skeletons of Radiolarians, and spicules of Sponges.

While the minute pelagic and deep-sea organisms above mentioned play by far the most important part in the formation of deep-sea deposits, the influence of Vertebrates is recognisable only in a very slight degree in some special regions by the presence of large numbers of sharks' teeth, and the ear-bones and a few other bones of whales. The otoliths of fish are usually present in the deposits, but, with the exception of two vertebræ and a scapula, no other bones of fish have been detected in the large amount of material we have examined.

Agents.—Having passed in review the various materials which go to the formation of deposits in the deep water immediately surrounding the land and in the truly oceanic areas, attention must now be directed to the agents which are concerned in the transport and distribution of these, and to the sphere of their action. The relations existing between the organic and inorganic elements of deposits to which we have just referred, and the laws which determine their distribution, will be pointed out at the same time.

The fluids which envelop the solid crust of the globe are incessantly at work disintegrating the materials of the land, which, becoming loose and transportable, are carried away, sometimes by the atmosphere, sometimes by water, to lower regions, and are eventually borne to the ocean in the form of solid particles or as matter in solution. The atmosphere when agitated, after having broken up the solid rock, transports the particles from the continents, and in some regions carries them far out to sea, where they form an appreciable portion of the deposit; as, for instance, off the west coast of North Africa and the south-west coast of Australia. Again, in times of volcanic eruptions, the dust and scoria which are shot into the air are carried immense distances by winds and atmospheric currents, and no small portion eventually falls into the sea.

Water is, however, the most powerful agent concerned in the formation and distribution of marine sediments. Running water corrodes the surface of the land, and carries the triturated fragments down into the ocean. The waters of the ocean, in the form of waves and tides, attack the coasts and distribute the debris at a lower level. Independently of the action of waves, there exist along most coasts currents, more or less constant, which have an effect in removing sand, gravel, and pebbles further from their origin. Generally, terrestrial matters appear to be distributed by these means to a distance of one or two hundred miles from the coast. Waves and currents probably have no erosive or transporting power at depths greater than 200 or 300 fathoms, and even at such depths it is necessary that there should be some local and special conditions in order that the agitated water may produce any mechanical effect. However, it is not improbable that, by a peculiar configuration of the bottom and ridges among oceanic islands, the deposit on a ridge may be disturbed by the tidal wave even at 1000 fathoms; and this may be the cause of the hard ground sometimes met with in such positions. By observations off the coast of France it has been shown that fine mud is at times disturbed at a depth of 150 fathoms; but, while admitting that this is the case on exposed coasts, the majority of observations indicate that beyond 100 fathoms it is an oscillation of the water, rather than a movement capable of exerting any geological action, which concerns us in this connection.

Although the great oceanic currents have no direct influence upon the bottom, yet they have a very important indirect effect on deposits, because the organisms which live in the warm equatorial currents form a very large part of the sediment being deposited there, and this in consequence differs greatly from the deposits forming in regions where the surface water is colder. In the same way a high or low specific gravity of the surface water has an important bearing on the animal and vegetable life of the ocean, and this in its turn affects the character of the deposits.

The thermometric observations of the *Challenger* show that a slow movement of cold water must take place in all the greater depths of the ocean from the poles, but particularly from the southern pole, towards the equator. It could be shown from many lines of argument that this extremely slow massive movement of the water can have no direct influence on the distribution of marine sediments.

Glaciers, which eventually become icebergs that are carried far out to sea by currents, transport detrital matter from the land to the ocean, and thus modify in the Arctic and Antarctic regions the deposits taking place in the regions affected by them. The detritus from icebergs in the Atlantic can be traced as far south as latitude 36° off the American coast, and in the southern hemisphere as far north as latitude 40°.

The fact that sea water retains fine matter in suspension for a much shorter time than fresh water should be referred to here as having an important influence in limiting the distribution of fine argillaceous and other materials borne down to the sea by rivers, thus giving a distinctive character to deposits forming near land.

We have pointed out the influence of temperature and salinity upon the distribution of the surface organisms whose skeletons form a large part of some oceanic deposits, and may state also that the bathymetrical distribution of calcareous organisms is influenced by the chemical action of sea water. We will return to these influences presently when describing the distribution of the various kinds of deposits and their reciprocal relations, especially in those regions of the deep sea far removed from the mechanical action of rivers, waves, and superficial currents. The action of life as a geological agent has been indicated under the heading *Materials*.

Methods.—We give here an example showing the order followed in describing the deposits examined:—

Station 338; lat. 21° 15′ S., long. 14° 2′ W.; March 21, 1876; surface temperature 76°·5, bottom temperature 36°·5, depth 1990 fathoms.

GLOBIGERINA OOZE, white with slight rosy tinge when wet; granular, homogeneous, and very slightly coherent when dry; resembles chalk.

i. *Carbonate of Calcium*, 90·38 per cent., consists of pelagic Foraminifera (80 per cent.); coccoliths and rhabdoliths (9 per cent.); Miliolas, Discorbinas, and other Foraminifera, Ostracode valves, fragments of Echini spines, and one or two small fragments of Pteropods (1·38 per cent.).

ii. *Residue*, 9·62 per cent., reddish brown; consists of—

1. *Minerals* [1·62] m. di. 0·45 mm., fragments of feldspar, hornblende, magnetite, magnetic spherules, a few small grains of manganese, and pumice.

2. *Siliceous Organisms* [1·00], Radiolarians, spicules of Sponges, and imperfect casts of Foraminifera.

3. *Fine Washings* [7·00], Argillaceous matter with small mineral particles and fragments of pumice and siliceous organisms.

The description of the deposits has been made upon this plan, which was adopted after many trials and much consideration.

This is not the place to give the reasons which have guided us in adopting this mode of description, or to give in detail the methods that we have systematically employed for all the sediments which we are engaged in describing. These will be fully given in the introduction to our *Challenger* Report. We limit ourselves here to explaining the meanings and arrangement of terms and abbreviations, so that the method may be understood and made available for others.

The description commences by indicating the kind of deposit (red clay, blue mud, Globigerina ooze, &c.), with the macroscopic characters of the deposit, when wet or dry.

We have always endeavoured to give a complete chemical analysis of the deposit, but when it was impossible to do this we have always determined the amount of *Carbonate of Calcium*. This determination was generally made by estimating the carbonic acid. We usually took a gramme of a mean sample of the substance for this purpose, using weak and cold hydrochloric acid. However, as the deposits often contain carbonates of magnesia and iron as well, the results calculated by associating the carbonic acid with the lime are not perfectly exact, but these carbonates of magnesia and iron are almost always in very small proportion, and the process is, we think, sufficiently accurate, for, owing to the sorting of the elements which goes on during collection and carriage, no two samples from the same station give exactly the same percentage. The number which follows the words "*Carbonate of Calcium*" indicates the percentage of $CaCO_3$; we then give the general designations of the principal calcareous organisms in the deposit.

The part insoluble in the hydrochloric acid, after the determination of the carbonic acid, is designated in our descriptions "*Residue.*" The number placed after this word indicates its percentage in the deposit; then follow the colour and principal physical properties. This residue is washed and submitted to decantations, which separate the several constituents according to their density; these form three groups—(1) *Minerals*, (2) *Siliceous Organisms*, (3) *Fine Washings*.

1. *Minerals.*—The number within brackets indicates the percentage of particular minerals and fragments of rocks. This number is the result of an approximate evaluation, of which we will give the basis in our report. As it is important to determine the dimensions of the grains of minerals which constitute the deposit, we give, after the contraction *m. di.*, their mean diameter in millimetres. We give next the form of the grains, if they are rounded or angular, &c.; then the enumeration of the species of minerals and rocks. In this enumeration we have placed the minerals in the order of the importance of the *rôle* which they play in the deposit. The specific determinations have been made with the mineralogical microscope in parallel or convergent polarised light.

2. *Siliceous Organisms.*—The number between brackets indicates the percentage of siliceous organic remains; we obtain it in the same manner as that placed after the word *Minerals*. The siliceous organisms and their fragments are examined with the microscope and determined. We have also placed under this heading the glauconitic casts of the Foraminifera and other calcareous organisms.

3. *Fine Washings.*—We designate by this name the particles which, resting in suspension, pass with the first decantation. They are about 0·05 mm. or less in diameter. We have been unable to arrange this microscopic matter under the category of *Minerals*, for, owing to its minute and fragmentary nature, it is impossible to determine the species. We have always found that the *Fine Washings* increase in quantity as the deposit passes to a clay, and it is from this point of view that the subdivision has its *raison d'être*. We often designate the lightest particles by the name argillaceous matter, but usually there are associated with this very small particles of indeterminable minerals and fragments of siliceous organisms. The number within brackets which follows the words *Fine Washings* is obtained in the same manner as those placed after *Minerals* and *Siliceous Organisms*.

These few words will suffice to render the descriptions intelligible. Greater details will be given, as already stated, in the *Challenger* Report. It may be added that in the majority of cases we have solidified the sediments and formed them into thin slides for microscopic examination, and that at all times the examination by transmitted light has been carried on at the same time as the examination by reflected light. Each description is followed by notes upon the dredging or sounding, upon the animals collected, and a discussion of the analysis whenever a complete analysis has been made, which is always the case with typical samples of the deposits.

Kinds of Deposits.—We now proceed to the description of the various types of deposits into which it is proposed to divide the marine formations that are now taking place in the deeper water of the various oceans and seas. We will speak first of those which are met with in the deeper water of inland seas, and around the coasts of continents and islands, and afterwards of those which are found in the abysmal regions of the great oceans. Those coast formations which are being laid down on the shores, or in very shallow water, and which have been somewhat carefully described previous to the recent deep-sea explorations, are here neglected.

A study of the collections made by the *Challenger* and other expeditions show—

(1) That in the deeper water around continents and islands which are neither of volcanic nor coral origin, the sediments are essentially composed of a mixture of sandy and amorphous matter, with a few remains of surface organisms, to which we give the name of *muds*, and which may be distinguished macroscopically by their colour. We distinguish them by the names, *blue*, *red*, and *green muds*.

(2) Around volcanic islands the deposits are chiefly composed of mineral fragments derived from the decomposition of volcanic rocks. These, according to the size of the grains, are called *volcanic muds or sands*.

(3) Near coral islands and along shores fringed by coral reefs, the deposits are calcareous, derived chiefly from the disintegration of the neighbouring reefs, but they receive large additions from shells and skeletons of pelagic organisms, as well as from animals living at the bottom. These are named, according to circumstances, *coral or coralline muds and sands*.

Let us now see what are the chief characteristics of each of these deposits.

Blue mud is the most extensive deposit now forming around the great continents and continental islands, and in all inclosed or partially inclosed seas. It is characterised by a slaty colour which passes in most cases into a thin layer of a reddish colour at the upper surface. These deposits are coloured blue by organic matter in a state of decomposition, and frequently give off an odour of sulphuretted hydrogen. When dried, a blue mud is grayish in colour, and rarely or never has the plasticity and compactness of a true clay. It is finely granular, and occasionally contains fragments of rocks 2 cm. in diameter; generally, however, the minerals, which are derived from the continents, and are found mixed up with the muddy matter in these deposits, have a diameter of 0·5 mm. and less. Quartz particles, often rounded, play the principal part, next come mica, feldspar, augite, hornblende, and all the mineral species which come from the disintegration of the neighbouring lands, or the lands traversed by rivers which enter the sea near the place where the specimens have been collected. These minerals make up the principal and characteristic portion of blue muds, sometimes forming 80 per cent of the whole deposit. Glauconite, though generally present, is never abundant in blue muds. The remains of calcareous organisms are at times quite absent, but occasionally they form over 50 per cent. The latter is the case when the specimen is taken at a considerable distance from the coast and at a moderate depth. These calcareous fragments consist of bottom-living and pelagic Foraminifera, Mollusks, Polyzoa, Serpulæ, Echinoderms, Alcyonarian-spicules, Corals, &c. The remains of Diatoms and Radiolarians are usually present. Generally speaking, as we approach the shore the pelagic organisms disappear; and on the contrary, as we proceed seawards, the size of the mineral grains diminishes, and the remains of shore and coast organisms give place to pelagic ones, till finally a blue mud passes into a true deep-sea deposit. In those regions of the ocean affected with floating ice, the colour of these deposits becomes gray rather than blue at great distances from land, and is further modified by the presence of a greater or less abundance of glaciated blocks and fragments of quartz.

Green Muds and Sands.—As regards their origin, composition, and distribution near the shores of continental land, these muds and sands resemble the blue muds. They are largely composed of argillaceous matter and mineral particles of the same size and nature as in the blue muds. Their chief characteristic is the presence of a considerable quantity of glauconitic grains, either isolated or united into concretions. In the latter case the grains are cemented together by a brown argillaceous matter, and include, besides quartz, feldspars, phosphate of lime, and other

minerals, more or less altered. The Foraminifera and fragments of Echinoderms and other organisms in these muds are frequently filled with glauconitic substance, and beautiful casts of these organisms remain after treatment with weak acid. At times there are few calcareous organisms in these deposits, and at other times the remains of Diatoms and Radiolarians are abundant. When these muds are dried they become earthy and of a gray-green colour. They frequently give out a sulphuretted hydrogen odour. The green colour appears sometimes to be due to the presence of organic matter, probably of vegetable origin, and to the reduction of peroxide of iron to protoxide under its influence. The *green sands* differ from the muds only in the comparative absence of the argillaceous and other amorphous matter, and by the more important part played by the grains of glauconite, which chiefly give the green colour to these sands.

Red Muds.—In some localities, as for instance off the Brazilian coast of America, the deposits differ from blue muds by the large quantity of ochreous matter brought down by the rivers and deposited along the coast. The ferruginous particles when mixed up with the argillaceous matter give the whole deposit a reddish colour. These deposits, rich in iron in the state of limonite, do not appear to contain any traces of glauconite, and have relatively few remains of siliceous organisms.

Volcanic Muds and Sands.—The muds and sands around volcanic islands are black or gray; when dried they are rarely coherent. The mineral particles are generally fragmentary, and consist of lapilli of the basic and acid series of modern volcanic rocks, which are scoriaceous or compact, vitreous or crystalline, and usually present traces of alteration. The minerals are sometimes isolated, sometimes surrounded by their matrix, and consist principally of plagioclases, sanadin, amphibole, pyroxene, biotite, olivine, and magnetic iron; the size of the particles diminishes with distance from the shore, but the mean diameter is generally 0·5 mm. Glauconite does not appear to be present in these deposits, and quartz is also very rare or absent. The fragments of shells and rocks are frequently covered with a coating of peroxide of manganese. Shells of calcareous organisms are often present in great abundance, and render the deposit of a lighter colour. The remains of Diatoms and Radiolarians are usually present.

Coral Muds.—These muds frequently contain as much as 95 per cent. of carbonate of lime, which consists of fragments of Corals, calcareous Algæ, Foraminifera, Serpulæ, Mollusks, and remains of other lime-secreting organisms. There is a large amount of amorphous calcareous matter, which gives the deposit a sticky and chalky character. The particles may be of all sizes according to the distance from the reefs, the mean diameter being 1 to 2 mm., but occasionally there are large blocks of coral and large calcareous concretions; the particles are white and red. Remains of siliceous organisms seldom make up over 2 or 3 per cent. of a typical coral mud. The *residue* consists usually of a small amount of argillaceous matter, with a few fragments of feldspar and other volcanic minerals; but off barrier and fringing reefs facing continents we may have a great variety of rocks and minerals. Beyond a depth of 1000 fathoms off coral islands the debris of the reefs begins to diminish, and the remains of pelagic organisms to increase; the deposit becomes more argillaceous, of a reddish or rose colour, and gradually passes into a Globigerina ooze or red clay. *Coral Sands* contain much less amorphous matter than coral muds, but in other respects they are similar, the sands being usually found nearer the reefs and in shallower water than the muds, except inside lagoons. In some regions the remains of calcareous algæ predominate, and in these cases the name *coralline mud or sand* is employed to point out the distinction.

Such is a rapid view of the deposits found in the deeper waters of the littoral zones, where the debris from the neighbouring land plays the most important part in the formation of muds and sands.

When, however, we pass beyond a distance of about 200 miles from land, we find that the deposits are characterised by the great abundance of fragmentary volcanic materials which have usually undergone great alteration, and by the enormous abundance of the shells and skeletons of minute pelagic organisms which have fallen to the bottom from the surface waters. These true deep-sea deposits may be divided into those in which the organic elements predominate, and those in which the mineral constituents play the chief part. We shall commence with the former.

(*To be continued.*)

THE TWO MANNERS OF MOTION OF WATER[1]

It has long been a matter of very general regret with those who are interested in natural philosophy that in spite of the most strenuous efforts of the ablest mathematicians the theory of fluid motion fits very ill with the actual behaviour of fluids, and this for unexplained reasons. The theory itself appears to be very tolerably complete, and affords the means of calculating the results to be expected in almost every case of fluid motion, but while in many cases the theoretical results agree with those actually obtained, in other cases they are altogether different.

If we take a small body, such as a raindrop, moving through the air, the theory gives us the true law of resistance; but if we take a large body, such as a ship moving through the water, the theoretical law of resistance is altogether out; and what is the most unsatisfactory part of the matter is that the theory affords no clue to the reason why it should apply to the one class more than to the other.

When seven years ago I had the honour of lecturing in this room on the then novel subject of vortex motion, I ventured to insist that the reason why such ill success had attended our theoretical efforts was because, owing to the uniform clearness or opacity of water and air, we can see nothing of the internal motion, and while exhibiting the phenomena of vortex rings in water, rendered strikingly apparent by partially colouring the water, but otherwise as strikingly invisible, I ventured to predict that the more general application of this method, which I may call the method of colour-bands, would reveal clues to those mysteries of fluid motion which had baffled philosophy.

To-night I venture to claim what is at all events a partial verification of that prediction. The fact that we can see as far into fluids as into solids naturally raises the question why the same success should not have been obtained in the case of the theory of fluids as in that of solids. The answer is plain enough. As a rule there is no internal motion in solid bodies, and hence our theory, based on the assumption of relative internal rest, applies to all cases. It is not, however, impossible that an at all events seemingly solid body should have internal motion, and a simple experiment will show that if a class of such bodies existed they would apparently have disobeyed the laws of motion.

These two wooden cubes are apparently just alike, each has a string tied to it. Now if a ball is suspended by a string you all know that it hangs vertically below the point of suspension, or swings like a pendulum; you see this one does so, the other you see behaves quite differently, turning up sideways. The effect is very striking so long as you do not know the cause. There is a heavy revolving wheel inside which makes it behave like a top.

Now what I wish you to see is that had such bodies been a work of Nature so that we could not see what was going on—if, for instance, apples were of this nature while pears were what they are, the laws of motion would not have been discovered, or if discovered for pears would not have applied to apples, and so would hardly have been thought satisfactory.

Such is the case with fluids. Here are two vessels of water which appear exactly similar, even more so than the solids, because you can see right through them, and there is nothing unreasonable in supposing that the same laws of motion would apply to both vessels. The application of the method of colour-bands, however, reveals a secret—the water of the one is at rest while that in the other is in a high state of agitation.

I am speaking of the two manners of motion of water—not because there are only two motions possible: looked at by their general appearance the motions of water are infinite in number; but what it is my object to make clear to-night is that all the various phenomena of moving water may be divided into two broadly distinct classes, not according to what with uniform fluids are their apparent motions, but according to what are the internal motions of the fluids which are invisible with clear fluids but which become visible with colour-bands.

The phenomena to be shown will, I hope, have some interest in themselves, but their intrinsic interest is as nothing compared to their philosophical interest. On this, however, I can but slightly touch. I have already pointed out that the problems of fluid motion may be divided into two classes, those in which the theoretical results agree with the experimental and those in which they are altogether different. Now what makes the recognition

[1] Lecture at the Royal Institution on Friday, March 28, by Prof. Osborne Reynolds, F.R.S.

of the two manners of internal motion of fluids so important is that all those problems to which the theory fits belong to the one class of internal motions. The point before us to-night is simple enough, and may be well expressed by analogy. Most of us have more or less familiarity with the motion of troops, and we can well understand that there exists a science of military tactics which treats of the best manœuvres to meet particular circumstances. Suppose this science proceeds on the assumption that the discipline of the troops is perfect, and hence takes no account of such moral effects as may be produced by the presence of an enemy. Such a theory would stand in the same relation to the movements of troops as that of hydrodynamics does to the movements of water. For although only disciplined motion may be recognised in military tactics, troops have another manner of motion when anything disturbs their order. And this is precisely how it is with water: it will move in a perfectly direct, disciplined manner under some circumstances, while under others it becomes a mass of eddies and cross streams, which may be well likened to a whirling struggling mob, where each individual element is obstructing the others. Nor does the analogy end here. The circumstances which determine whether the motion of troops shall be a march or a scramble are closely analogous to those which determine whether the motion of water shall be direct or sinuous. In both cases there is a certain influence necessary for order: with troops, it is discipline; with water, it is viscosity or treaclyness. The better the discipline of the troops, or the more treacly the fluid, the less likely is steady motion to be disturbed under any circumstances. On the other hand, speed and size are in both cases influences conducive to unsteadiness. The larger the army and the more rapid the evolutions the greater the chance of disorder; so with fluid, the larger the channel and the greater the velocity the more chance of eddies. With troops some evolutions are much more difficult to effect with steadiness than others, and some evolutions which would be perfectly safe on parade would be sheer madness in the presence of an enemy. It is much the same with water.

One of my chief objects in introducing this analogy is to illustrate the fact that even while executing manœuvres in a steady manner there may be a fundamental difference in the condition of the fluid. This is easily realised in the case of troops, difficult and easy manœuvres may be executed in equally steady manners if all goes well, but the conditions of the moving troops are essentially different, for while in the one case any slight disarrangement would be easily rectified, in the other it would inevitably lead to a scramble. The source of such a change in the manner of motion may be ascribed either to the delicacy of the manœuvre or to the upsetting disarrangement, but as a matter of fact both these causes are necessary. In the case of extreme delicacy an indefinitely small disturbance, such as is always to be counted upon, will effect the change. Under these circumstances we may well describe the condition of the troops in the simple manœuvre as stable, while that in the difficult manœuvre is unstable. *i.e.* will break down on the smallest disarrangement. The small disarrangement is the immediate cause of the breakdown in the same sense as the sound of a voice is sometimes the cause of an avalanche, but since such disarrangement is certain to occur a condition of instability is the real cause of the change.

All this is exactly true for the motion of water. Supposing no disarrangement, the water would move in the manner indicated in the theory, just as if there were no disturbance an egg would stand on its end, but as there is always some slight disturbance it is only when the condition of steady motion is more or less stable that it can exist. In addition then to the theories either of military tactics or of hydrodynamics, it is necessary to know under what circumstances the manœuvres of which they treat are stable or unstable. It is in definitely separating these that the method of colour-bands has done good service, which will remove the discredit in which the theory of hydrodynamics has been held.

In the first place it has shown that the property of viscosity or treaclyness possessed more or less by all fluids is the general influence conducive to steadiness, while, on the other hand, space and velocity have the counter influence. Also that the effect of these influences is subject to a perfectly definite law, which is that a particular evolution becomes unstable for a definite value of the viscosity divided by the product of the velocity and space. This law explains a vast number of phenomena which have hitherto appeared paradoxical. One general conclusion is that with sufficiently slow motion all manners of motion are stable.

The effect of viscosity is well shown by introducing a band of coloured water across a beaker filled with clear water at rest. Then, when all is quite still, turn the beaker about its axis. The glass turns, but not the water, except that which is quite close to the glass. The coloured water which is close to the glass is drawn out into what looks like a long smear, but it is not a smear. It is simply a colour-band extending from the point in which the colour touched the glass in a spiral manner inwards; showing that the viscosity is slowly communicating the motion of the glass to the water within. To show this it is only necessary to turn the beaker back, and the smear closes up until the colour-band assumes its radial position. Throughout this evolution the motion has been quite steady—quite according to the theory.

When water flows steadily, it flows in streams. Water flowing along a pipe is such a stream. This is bounded by the solid surface of the pipe, but if the water is flowing steadily we can imagine the water to be divided by ideal tubes into a faggot of indefinitely small streams, any one of which may be coloured without altering its motion, just as one column of infantry may be distinguished from another by colour.

If there is internal motion, it is clear that we cannot consider the whole stream bounded by the pipe as a faggot of elementary streams, as the water is continually crossing the pipe from one side to another, any more than we can distinguish the streaks of colour in a human stream in the corridor of a theatre.

Solid walls are not necessary to form a stream. The jets from a fountain or the cascade in Niagara are streams bounded by free surfaces. A river is a stream half bounded by a solid surface. Streams may be parallel, as in a pipe; converging or diverging, as in conical pipes; or they may be straight and curved. All these circumstances have their influence on stability in the manner indicated in the accompanying diagram.

CIRCUMSTANCES CONDUCIVE TO

Direct or Steady Motion	*Sinuous or Unsteady Motion*
(1) Viscosity or fluid friction which continually destroys disturbance. Thus treacle is steadier than water.	(5) Particular variation of velocity across the stream, as when a stream flows through still water.
(2) A free bounding surface.	(6) Solid bounding walls.
(3) Converging solid boundaries.	(7) Diverging solid bounding walls.
(4) Curvature of the streams with the velocity greatest on the outside.	(8) Curvature with the velocity greatest on the inside.

It has for a long time been noticed that a stream of fluid through fluid otherwise at rest is in an unstable condition. It is this instability which renders flames and jets sensitive to the slight disarrangement caused by sound.

I have here a glass vessel of clean water in front of the lantern, so that any colour-bands will be projected on to the screen. You see the ends of two vertical tubes facing each other: nothing is flowing through these tubes, and the water in the vessel is at rest. I now open two taps, so as to allow a steady stream of coloured water to enter at the lower pipe, water flowing out at the upper. The water enters quite steadily, forms a sort of vortex ring at the end, which proceeds across the vessel, and passes out at the lower pipe. The coloured stream then extends straight across the vessel, and fills both pipes: you see no motion; it looks like a red glass rod. The red water is, however, flowing slowly, so slowly that viscosity is paramount, and hence the stream is steady. As the speed is increased, a certain wriggling, sinuous motion appears in the column; a little faster and the column breaks up into beautiful and well-defined eddies, and spreads into the surrounding water, which, becoming opaque with colour, gradually draws a veil over the experiment. The final breaking up of the column was doubtless determined by some slight vibration in the apparatus, but such vibration, which is always going on, will not affect the stream until it is in a sufficiently unstable condition. The same is true of all streams bounded by standing water.

If the motion is sufficiently slow, according to the size of the stream and the viscosity, the stream is steady and stable. Then at a certain critical velocity, determined by the ratio of the viscosity of the water to the diameter of the stream, the stream becomes unstable. So that under any conditions which involve a stream through surrounding water, the motion becomes unstable at sufficiently great velocities.

Now one of the most noticeable facts in experimental hydrodynamics is the difference in the way in which water flows along contracting and expanding channels. Such channels are now projected on the screen, surrounded and filled with clean, still water. The mouth of the tube at which the water enters is wide; the tube then contracts for some way, then expands again gradually until it is as wide as at the mouth. At present nothing is to be seen of what is going on. On colouring one of the elementary streams, however, outside the mouth, a colour-band is formed. This colour-band is drawn in with the surrounding water, and shows what is going on. It enters quite steadily, preserving its clear streak-like character until it has reached the neck, where convergence ceases; then on entering the expanding channel it is altogether broken up into eddies. Thus the motion is direct and steady in the contracting tube, sinuous in the expanding.

The theory of hydrodynamics affords no clue to the cause of this difference, and even as seen by the method of colour-bands the reason for the sinuous motion is not obvious. If the current be started suddenly at the first instant, the motion is the same in both parts of the channel. Its changing in the expanding pipe seemed to imply that there the motion is unstable. If this were so, it ought to appear from the theory. I am ashamed to think of the time spent in trying to make this out from the theory without any result. I then had recourse to the method of colour again, and found that there is an intermediate stage.

When the tap is first opened, the immediately ensuing motion is nearly the same in both parts; but, while that in the contracting tube maintains its character, that in the expanding changes its character: a vortex ring is formed which, moving forwards, leaves the motion behind that of a parallel stream through the surrounding water. When the motion is sufficiently slow, the stream is stable, as already explained; there is then direct motion in both the contracting and expanding portions of the tube, but these are not similar, the first being a faggot of similar elementary contracting streams, the latter being that of one parallel stream through surrounding fluid. The first is a stable form, the second an unstable, and on increasing the velocity the first remains, while the second breaks down, and, as before, the expanding tube is filled with eddies. This experiment is typical of a large class of motions. Whenever fluid flows through a narrow neck, as it approaches the neck it is steady, after passing the neck it is sinuous. The same is produced by an obstacle in the middle of a stream, and virtually the same by the motion of a solid through the water.

The object projected on the screen is not unlike a ship. Here the ship is fixed and the water flowing past it, but the effect would be the same were the ship moving through the water. In the front of the ship the stream is steady, so long as it contracts, until it has passed the middle; you then see the eddies formed as the streams expand again round the stern. It is these eddies which account for the difference between the actual and theoretical resistance of ships.

It appears then that the motion in the expanding channel is sinuous, because the only steady motion is that of a stream through still water. Numerous cases in which the motion is sinuous may be explained in the same way, but not all. If we have a parallel channel, neither contracting or expanding, the steady moving streams will be a faggot of steady parallel elementary streams all in motion but having different velocities, those in the middle moving the fastest. Here we have a stream but not through standing water. When this investigation began, it was not known whether such a stream was ever steady; but there was a well-known anomaly in the resistance encountered in parallel channels. In rivers and all pipes of sensible size experience had shown that the resistance increased as the square of the velocity, whereas in very small pipes, such as represent the smaller veins in animals, Poiseuille had proved that the resistance increased as the velocity. Thus since the resistance would be as the square of the velocity with sinuous motion, and as the velocity in the case of direct motion, it appeared that the discrepancy would be accounted for if it could be shown that the motion becomes unstable at sufficiently large velocities according to the size of the pipe. This has been done. You see on the screen a pipe with its end open. It is surrounded by water, and by opening a tap I can draw the water through it. This makes no difference to the appearance until I colour one of the elementary streams, when you see a beautiful streak of colour extend all along the pipe. So far the stream has been running steadily, and it appears quite stable. As the speed increases the colour-band naturally becomes finer, but on reaching a certain speed the colour-band becomes unsteady and mixes with the surrounding fluid filling the pipe. This sinuous motion comes on at a definite velocity; diminish the velocity ever so little, the band becomes straight and clear, increase it again and it breaks up. This critical speed depends on the size of the tube in the exact inverse ratio, the smaller the tube the greater the velocity. Also the more viscous the fluid the greater the velocity.

We have here then not only a complete explanation of the difference in the laws of resistance generally experienced and that found by Poiseuille, but also we have complete evidence of the instability of steady streams flowing between solid surfaces. The cause of this instability is not yet completely ascertained, but this much is certain, that while lateral stiffness in the walls of the tube is unimportant, inextensibility or tangential rigidity is essential to the creation of eddies. I cannot show you this, because the only way in which we can produce the necessary condition is by wind blowing over the surface of water. When the wind blows over water it imparts motion to the surface of the water just as a moving solid surface. Moving in this way the water is not susceptible of eddies, it is unstable, but the result is waves. This is proved by a very old experiment, which has recently attracted considerable notice. If oil be put on the surface it spreads out into an indefinitely thin sheet with only one of the characteristics of a solid surface, it offers resistance, very slight, but still resistance to extension or contraction. This resistance, slight as it is, is sufficient to entirely alter the character of the motion. It renders the motion of the water unstable internally, and instead of waves what the wind does is to produce eddies beneath the surface. To those who have observed the phenomenon of oil preventing waves there is probably nothing more striking throughout the region of mechanics. A film of oil so thin that we have no means of illustrating its thickness, and which cannot be perceived except by its effects—which possesses no mechanical properties that can be made apparent to our senses—is yet able to prevent an action involving forces the strongest that we can conceive, able to upset our ships and destroy our coasts. This, however, becomes intelligible when we perceive that the action of the oil is not to calm the sea by sheer force, but merely, as by its moral force, to alter the manner of motion produced by the action of the wind from that of the terrible waves on the surface into the harmless eddies below. The wind brings the water into a highly unstable condition, into what morally we should call a condition of great excitement; the oil by an influence we cannot perceive directs this excitement. This influence, although insensibly small, is however now proved to be of a mechanical kind, and to me it seems that this instance of one of the most powerful mechanical actions of which the forces of Nature are capable being entirely controlled by a mechanical force so slight as to be imperceptible does away with every argument against strictly mechanical sources for what we may call mental and moral forces.

But to return to the instability in parallel channels. This has been the most complete as well as the most definite result of the method of colour-bands. The circumstances are such as render definite experiments possible; these have been made and reveal a definite law of instability, which law has been tested by reference to all the numerous and important experiments that have been recorded with reference to the law of resistance in pipes, whence it appears that the change in the variation of the resistance from the velocity to the square of the velocity agrees as regards the velocity at which it occurs with the change from stability to instability. It is thus shown that water behaves in exactly the same manner, whether the channel is, as in Poiseuille's experiments, of the size of a hair, or whether it be the size of a water main or of the Mississippi. The only difference being that in order that the motions may be compared the velocities must be inversely as the size of the channels. This is not the only point explained.

If we consider other fluids than water, some fluids like oil or treacle apparently flow more slowly and steadily than water; this however is only in smaller channels. The velocity at which sinuous motion commences increases with the viscosity. Thus while water in ordinary streams is always above its critical velocity and the motion sinuous, the motion of treacle in such streams as we see is below its critical velocity and the motion is steady. But if Nature had produced rivers of treacle the size of the Thames the treacle would have flowed as easily as water. Thus in the lava streams from a volcano, although looked at closely the lava has the consistency of a pudding, in the large and rapid streams down the mountain side the lava flows with eddies like water.

There is now only one experiment left. This relates to the effect of curvature in the streams on the stability of the motion. Here again we see the whole effect altered by apparently a very slight cause. If the water be flowing in a bent channel in steady streams, the question as to whether the motion will be stable or not turns on the variation of the velocity across the channel. In front of the lantern is a cylinder with glass ends, so that the light passes through in the direction of the axis. The cylinder is full of water, the disk of light on the screen being the light which passes through this water, and is bounded by the circular walls of the cylinder. By means of two tubes temporarily attached, a stream of colour is introduced so as to form a colour-band right across the cylinder, extending from wall to wall; the motion is very slow, and, the taps being closed and the tubes removed, the colour-band is practically stationary. The vessel is now caused to revolve about its axis. At first only the walls of the cylinder move, but the colour-band shows that the water gradually takes up the motion, the streak being wound off at the ends into two spiral lines, but otherwise remaining still and vertical; when the streak is all wound off and the spirals meet in the middle, the whole water is in motion. But as the vessel is revolving, the motion is greatest at the outside, and is thus stable. There are no eddies, although the spiral rings are so close as nearly to touch each other. The vessel stops, and gradually stops the water, beginning at the outside. If this went on steadily, the spirals would be unwound and the streak restored; but as the velocity is now greater towards the centre, the motion is unstable for some distance from the outside, and eddies form, breaking up the spirals for a certain distance towards the middle, but leaving the middle revolving steadily. Besides indicating the effect of curvature, this experiment neatly illustrates the action of the earth's surface on the air moving over it, the variation of temperature having much the same effect on the stability of the moving fluid as the curvature of the vessel. The moving air is unstable for a few thousand feet above the earth's surface, and the motion consequently sinuous to this height. The mixing of the lower and upper strata produces the heavy cumulus clouds, but above this the influence of the temperature predominates; the motion is stable, and clouds, if they form, are stratus, like the inner spirals of the colour-bands.

REPORT ON ATMOSPHERIC SAND-DUST FROM UNALASKA[1]

THE specimen of sand which fell during a rain-storm, October 20, 1883, at Unalaska, Alaska, has been submitted to microscopical analysis, and found to be undoubtedly of volcanic origin. It is gray, and the grains are rather uniform in size, rarely attaining a diameter of 0·35 mm. Under a hand lens can be distinguished light-coloured crystals and fragments which are occasionally glassy in lustre, mixed with others of darker colours; both are more or less dusty in appearance from the presence of finer particles. For convenience of manipulation and preservation, as well as to render the optical tests more definite and decisive, the sand was mounted in Canada balsam upon glass slides, after the manner of thin sections of rocks for microscopical investigations. It is composed chiefly of either broken or complete crystals of feldspar, augite, hornblende, and magnetite, with numerous fragments of ground-mass and a few small particles of glass freighted with grains of iron oxide or other heavy minerals. The feldspar frequently occurs in well-preserved crystals. Cleavage plates are common, but irregular fragments predominate. A few thin cleavage lamellæ parallel to the base between crossed nicols show no bending due to polysynthetical twinning, and extinction takes place when the lines which indicate the clinopinacoidal cleavage are parallel to the principal section of either nicol. While it is evident that such thin plates are orthoclase, the prevailing feldspar is undoubtedly basic plagioclase, for chemical analysis shows the sand to contain only 52·48 per cent. SiO_2. The perfect crystals are usually about 0·15 × 0·13 mm. in size, and slightly tabular, parallel to the clinopinacoid. At times they present an almost hexagonal aspect, and generally contain inclusions so abundantly as to render the middle portion feebly translucent. Among the imprisoned particles may be recognised hornblende microlites, grains of iron oxide with crystallites of an indeterminable nature, and their arrangement frequently imparts a distinct zonal structure to the feldspar. The hornblende, which is not nearly as prominent a constituent of the sand as the feldspar, occurs chiefly in cleavage plates and irregular angular fragments. It has a brown to dark brown colour, with deep absorption and strong pleochroism, as in the andesite which it characterises. The size of the hornblende fragments varies within small limits, averaging 0·10 × 0·05 mm., and the extinction angle is about 9°. It occasionally contains numerous crystallites arranged parallel to the vertical (c'') axis. In the number of slides examined several brownish foliæ, apparently of biotite, were observed under such circumstances that their characterising optical properties could not be satisfactorily determined. Of the FeMg silicates augite is the most abundant. It is of a pale green colour, non-pleochroitic, and its angle of extinction as seen in the cleavage plates is about 46°. Like hornblende, it is found generally in irregular fragments. The prismatic fragments vary from 0·10 to 0·35 mm. in greatest length. The grains of magnetite, which may, in considerable quantities, be readily picked out of the sand with a magnet, are for the most part of irregular outline and small size. Instead of forming independent grains of themselves, they are generally found cleaving to fragments of the ground-mass, or included in the other minerals.

Besides the mineral ingredients already mentioned, the sand contains numerous irregular grains swarming with clear crystallites and microlites embedded in a grayish translucent to transparent, often amorphous, base. These composite fragments correspond to the ground-mass of the eruptive rocks to which the volcanic sand is allied. They vary in size up to a diameter of 0·26 mm., and are generally rendered heavier than they would otherwise be by small particles of magnetite or augite. The crystal fragments frequently have portions of the ground-mass attached to them, and present that ragged appearance which distinguishes volcanic sand from that which has been produced by other methods. Feldspar, augite, hornblende, magnetite, with fragments of the ground-mass, make up the bulk of the sand. Its composition is that of a hornblende-andesite very like those which occur at many points along the western coast. One is surprised to find a conspicuous deficiency in the most common and generally prevailing element of volcanic ashes. It is true that clear or sparingly microlitic glass particles are found in the sand from Unalaska, but they are rather exceptional and uncommon. This paucity in glass fragments may be readily comprehended by reflecting upon the origin and distribution of volcanic ashes.

The United States Geological Survey party sent out last summer in my charge under the direction of Capt. Dutton for the reconnaissance of the southern portions of the Cascade Range, collected a lot of volcanic sand about a dozen miles north-east of Mount Shasta. It does not form a thick deposit, but is widespread over the basaltic slopes south of Sheep Rock, and like that collected at Unalaska consists chiefly of crystal fragments, of which feldspar is the most abundant. Hornblende, hypersthene, augite, and magnetite are less prominent. In addition to these and numerous fragments of microlitic ground-mass, there are many clear or sparingly crystallitic glass particles of a pumiceous character. The composition of the sand is that of a hypersthene-bearing hornblende-andesite like that which forms the well-preserved and prominent crater springing up from the north-western slope of Mount Shasta, about two miles from that summit. This crater is the counterpart of Shasta cone, when we consider the whole volcanic pile, and has been christened Shastina by Capt. Dutton to indicate the relation it bears to its majestic neighbour. In the volcanic sand which travelled about a dozen miles north-east from Shastina, grains may be found having a diameter of 0·5 mm., so that it is, on the whole, considerably coarser and less uniform than that which fell at Unalaska, October 20, 1883, but like the latter it is made up chiefly of fragments of crystalline matter.

On the other hand, volcanic dust which has been carried long distances is composed principally of glass particles, and there is a conspicuous paucity of crystals and fragments of dense microlitic ground-mass. That which emanated from a crater in Iceland and fell over Norway and Sweden March 29 and 30, 1875, more than 750 miles from its source, is composed almost exclusively of sharp-edged angular glass fragments with curved sides. These splinters, chips, and shards of glass show by their more or less curved outlines, as well as by their tubular or vesicular structure, that they differ from pumice only in being fragmental. In the formation of pumice the inflation and distension by inclosed steam and gases is carried so far as to produce a froth, but if the same process be continued until explosion takes place,

[1] By J. S. Diller, Assistant Geologist, United States Geological Survey.

volcanic dust will be the result. The same might be said of the Krakatoa dust which has been collected far from its source. That which fell August 27 at Batavia, about sixty miles from Krakatoa, according to Renard, consists chiefly of glass particles, with plagioclase, augite, rhombic pyroxene, and magnetite, giving the general composition found in some augite-andesites In Krakatoa dust and pumice obtained from various localities in the vicinity of the Java coast, I have always found glass the most abundant constituent. The rhombic pyroxene, hypersthene, predominates largely over augite, and as Mr. Iddings has already shown, the ejected material belongs to hypersthene-andesite very like the pumiceous variety of the same rock upon the south-western slope of Mount Shasta in the Cascade Range.

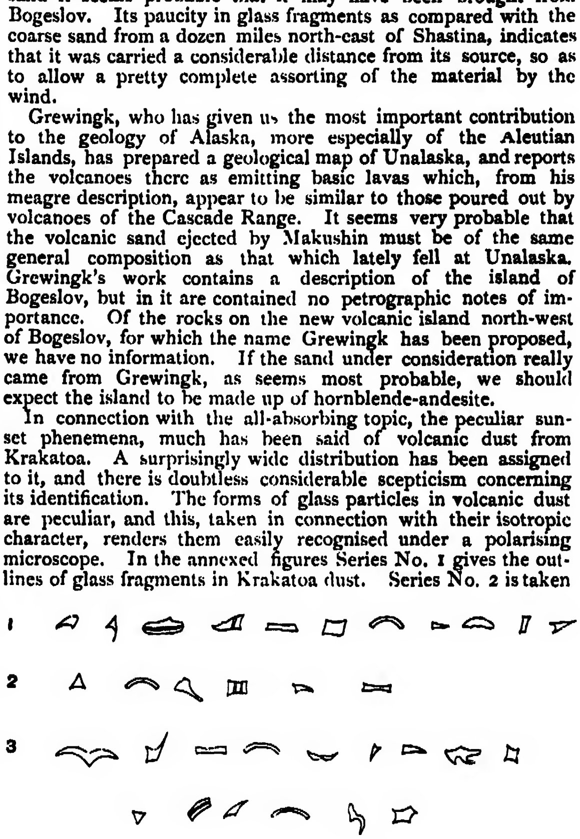
While it is evident that all kinds of ejected material, from the finest dust to the coarsest fragments, may be found upon their parent cone, yet it is true that all ashes which have been transported by the winds for distances greater than one hundred miles are composed chiefly of glass fragments distinguished by their pumiceous character. Volcanic glass may be considered an almost inevitable product of violent eruptions; and of all the important constituents of sand and dust formed in this way, it is the lightest. Furthermore, for a reason easily explained, it is blown to much finer dust-particles than any of the products of crystallisation. In a magma where crystallisation is taking place, the absorbed gases and uncombined water under enormous tension are gradually accumulated in that portion which is most liquid and least individualised. In this way the portion of the magma which upon solidification yields glass becomes stored with the energy that will cause its distension and perhaps blow it to atoms when the mass is relieved from the antagonising pressure. The individualised and unindividualised portions of the magma may be irregularly commingled, or they may arrange themselves, as is frequently the case in obsidians from Oregon, in more or less regular alternating bands. The streams of microlites must necessarily imprison less uncombined water or absorbed gases than the bands between them, so that when the pressure is relieved the latter will suffer the greatest amount of distension. If the tension of the confined water and gases is great enough, the amorphous portion of the magma may be blown to glassy dust, while the individualised portion, pulverised rather by external than internal forces, is not reduced to so high a degree of fineness. Volcanic dust is the extreme term of a series which begins in compact lava, and has for its middle members pumice in different stages of inflation. It appears to be a significant fact, at least as far as I have had an opportunity to observe, that effused pumice, *i.e.* pumice which occurs in places as froth upon a stream of obsidian into which it gradually passes, is highly microlitic. The glassy partitions which bound the more or less rounded vesicles are crowded with microlites and crystallites, while in ejected pumice where long, distended vesicles prevail, or in volcanic glass dust, the products of crystallisation are comparatively few or entirely wanting.

Prof. F. W. Clarke, chief chemist of the United States Geological Survey, has determined the amount of silica in the sand which fell at Unalaska, as well as that from the north-eastern slope of Mount Shasta. The former contains 52·48 SiO_2. As should be expected, it is more basic than hornblende-andesite, and indicates that the acid portion of the magma—the volcanic glass in the form of dust—was blown away from the sand. It is well known that the glassy base is in general the most acid portion of a rock, and any mechanical means by which the magma is separated into crystal sand and glass dust divides the rock into a basic and acidic portion. This division is in certain degrees indicated by the analysis of Renard and Iddings of material from the recent eruption of Krakatoa. The pumice contained only 62 per cent. of SiO_2, while the dust which fell at Batavia, according to Renard, contained 65per cent. of SiO_2. The few observations I have been able to gather indicate that even under favourable circumstances volcanic sand is not carried a hundred miles from its source, while dust from the same vent may be distributed over many hundreds of miles beyond the sand.

It is unfortunate that we do not possess more definite and detailed knowledge with reference to the source and distribution of the volcanic sand from Unalaska. Mr. Applegate, in his letter of transmittal dated October 22, says, "I forward by this mail a sample bottle of sand that fell during the storm of October 20, 1883. At 2.30 p.m. the air became suddenly darkened like night, and soon after a shower of mixed sand and water fell for about ten minutes, covering the ground with a thin layer. The windows were so covered that it was impossible to see through them. This sand is supposed to have come either from the Makushin or the new volcano adjacent to Bogeslov. The former is a distance of about nineteen miles to the south-west, but for years has only issued forth smoke or steam. The latter is a new one which made its appearance this summer, and burst out from the bottom of Behring Sea. It has been exceedingly active, and has already formed an island from 800 to 1200 feet high. Bogeslov is about sixty miles from here (Unalaska) in a west direction. The new volcano is about one-eighth of a mile north-west of it." Judging alone from the size of the grains of sand it seems probable that it may have been brought from Bogeslov. Its paucity in glass fragments as compared with the coarse sand from a dozen miles north-east of Shastina, indicates that it was carried a considerable distance from its source, so as to allow a pretty complete assorting of the material by the wind.

Grewingk, who has given us the most important contribution to the geology of Alaska, more especially of the Aleutian Islands, has prepared a geological map of Unalaska, and reports the volcanoes there as emitting basic lavas which, from his meagre description, appear to be similar to those poured out by volcanoes of the Cascade Range. It seems very probable that the volcanic sand ejected by Makushin must be of the same general composition as that which lately fell at Unalaska. Grewingk's work contains a description of the island of Bogeslov, but in it are contained no petrographic notes of importance. Of the rocks on the new volcanic island north-west of Bogeslov, for which the name Grewingk has been proposed, we have no information. If the sand under consideration really came from Grewingk, as seems most probable, we should expect the island to be made up of hornblende-andesite.

In connection with the all-absorbing topic, the peculiar sunset phenemena, much has been said of volcanic dust from Krakatoa. A surprisingly wide distribution has been assigned to it, and there is doubtless considerable scepticism concerning its identification. The forms of glass particles in volcanic dust are peculiar, and this, taken in connection with their isotropic character, renders them easily recognised under a polarising microscope. In the annexed figures Series No. 1 gives the outlines of glass fragments in Krakatoa dust. Series No. 2 is taken



from the volcanic dust which fell in Norway and Sweden, March 29 and 30, 1875. Series No. 3 represents the curious fragments found in an old quartz-porphyry tufa at Breakheart Hill, in Sangus, north of Boston. The forms of glass particles seen in the volcanic dust collected by Mr. Russell near the Truckee River are represented in Series No. 4. The fragments represented in Series No. 3 are now chiefly quartz, but were once particles of volcanic glass, and show that in the early geological history of Eastern Massachusetts there were volcanoes belching forth volcanic ashes like that of recent times, and flooding the country with acid lavas whose beautiful and regular fluidal banding has puzzled many observers and led them to suspect its sedimentary origin. It seems reasonable to suppose that the Grewingk crater must have yielded dust as well as sand, and that the former can, with a high degree of probability, be distinguished from the dust of Krakatoa. The glass dust from Grewingk, judging from that seen in the Unalaska sand, is less clouded than that from Java. In the Krakatoa dust it is hypersthene which is associated with the feldspar, augite, and magnetite, but in Grewingk dust we should expect to find hornblende.

A complete knowledge of the distribution of volcanic sand and dust has such an important bearing upon meteorological conditions, as well as upon volcanic phenomena, that it is hoped accurate and continuous observations may be made upon this subject at suitable meteorological stations. When we consider the dust in cities rising from the ground into the air during dry weather, as well as contributions, frequently glassy, made by

various furnaces and factories, it is evident that observations for meteoric and volcanic dust should be made at elevated stations far removed from large cities. If a station were established upon Mount Shasta, California, as suggested by Mr. Gilbert Thompson, it would afford excellent opportunity for such observations. The station on Mount Washington is also favourably situated, and if regular observations were made at these stations and in Alaska for small as well as large quantities of such dust, and the sediments collected subjected to microscopical examination, the result would doubtless be of great interest.

Washington, D.C., March 25

THE POLAR CONFERENCE[1]

THE Fellows need hardly be reminded that it was at the suggestion of an Austrian, the late Carl Weyprecht, that this great international undertaking was set on foot, and accordingly Vienna was the most fitting city in which to welcome the several expeditions on their return to civilisation, and to discuss the best mode of utilising their labours.

The chiefs of nine expeditions were present at the meeting. The unrepresented stations were the two Russian ones, at Nova Zemlya and at the mouth of the Lena (at which latter station the observations will be continued until August 1884); that established by the Society of Science of Finland at Sodankylä, the German station in South Georgia, and the second American station at Lady Franklin Bay. As to the fate of the observers at the last-named locality there are unfortunately grave reasons for anxiety.

Most of the expeditions had brought home a collection of photographs, giving a vivid representation of their respective surroundings during their sojourn. Many of these possess ethnological interest, and one was humorous, as it showed the Dutch Arctic tin band, with instruments made out of preserved meat canisters.

I suppose my audience is aware that the Dutch Expedition was ice-bound and drifted about in the Kara Sea, ultimately saving itself in its boats. The ship was crushed in the autumn of 1882, but did not actually sink for six months, so that all the property was saved. Under such circumstances, however, it is no wonder that no magnetical observations were made.

As regards the publications, these are to be carried out independently in each country, but on a uniform plan. The meteorological observations are to be given in metric and centigrade measures; the magnetical according to the C.G.S. system of units.

The hourly observations are to be published in detail. The barometer observations are not to be corrected for gravity, but the value of this correction is to be given in the tables.

As regards terrestrial magnetism, besides the publication of the term day observations a detailed reproduction of all the observations for certain days of disturbance is to be given. A list of these days will be prepared by Prof. Wild.

All the members of the Conference are requested to collect data for earth currents for their respective countries during the period of the circumpolar observations. The auroral observations are to be published on the scheme proposed by Weyprecht.

As to the magnetic disturbances and their elimination there was, as might be expected, a long debate, but no definite resolutions were adopted.

The publication of a number of observations was left optional, such as evaporation, solar radiation, the resolution of the wind to four components, the calculation of wind-roses according as the pressure was above or below 760 mm., &c.

It is hoped that the whole of the results will have appeared by the end of 1885.

The Conference was most graciously received by the Emperor at an audience. The members were also entertained at a magnificent banquet on April 23 by Count Wilczek, at whose sole expense the Austrian Expedition to Jan Mayen had been fitted out and maintained during its stay.

The detailed report of the proceedings of the Conference will be published in French and German, and will appear before long.

GEOLOGY IN RUSSIA

ALTHOUGH a large amount of geological work has been done in Russia, especially during the last twenty years, the geological exploration of this wide region has not been carried on in the detailed and accurate manner required by modern geology. An important step towards the attainment of more precise knowledge on this subject was taken in 1882 by the formation of a special Geological Commission intrusted with the geological survey of Russia. A yearly subsidy of 30,000 roubles was granted for that purpose by the State, to which must be added various occasional subsidies for special aims, supplied either by Government or by provincial assemblies and private bodies. This Commission has now published two volumes of its *Bulletin* and one fasciculus of *Memoirs*.[1] From these we learn that the chief work undertaken has been the preparation of a geological map of Russia on the scale of 10 versts (6·7 miles) to an inch. Russia has been divided into ten regions: Baltic, Central, Dnieper, Western Frontier, Volga and Don, Caspian, Ural, Crimea and Caucasus, Northern, and Finland. The survey has been started in several regions at once, each region being subdivided into three parts: (1) those which are well explored, and the maps of which already exist and could be employed for geological purposes; (2) those in which various isolated explorations have been made; and (3) unexplored parts. The explorations will be prosecuted first of all in the second of these three areas. The system of colours for the map will be adopted which was recommended by the Congress of Bologna. The explanations, as also the chief names, will be printed in French, side by side with the Russian text.

The first volume of the *Memoirs* contains a work by M. Lahusen, on the Jurassic fauna of the Government of Ryazan, written in Russian, with a summary in German. It is a complete enumeration of the Jurassic fossils of the region, the deposits of which belong—the black clay, with *Cardioceras cordatum*, to the Lower Oxfordian; the oolitic gray clay, with iron and *Cardioceras lamberti*, to the Upper Callovian; the gray and brown clays, with *Perisphinctes mosquensis* and *mutatus*, to the Middle; and the brown iron sandstone, with sheets of black clay and characterised by *Cosmoceras gowerianum*, *Cardioceras chamusseti*, and *Stephanoceras elatinæ*, to the Lower Callovian. The new fossils of the *Aucella* sandstone will be described by M. Nikitin. Eleven quarto plates illustrating a great number of species, many of which are new, accompany the paper.

The *Bulletin* (*Izvestia*) contains, besides the minutes of meetings, a number of preliminary reports of the geologists of the Survey, and the description, by M. Nikitin, of the sheet 58 (*Yaroslavl*) of the geological map of Russia. These notices are full of valuable information regarding the details of the geological structure of Russia. Among papers of more general interest we may mention Prof. Fr. Schmidt's report upon his explorations on the Baltic Railway, which embodies the results of his prolonged researches in the same region (vol. ii. fasc. 5). It has long been known that Esthonia is built up of Silurian formations, from beneath which rises the Cambrian Ungulite sandstone characterised by *Obolus apollinis*. After the emergence of the Silurian deposits, the country remained for a vast period a barren land undergoing atmospheric denudation. During this long lapse of time the terrace of the Glint, which runs from Lake Ladoga to Baltisch Port, was formed. During the Glacial period the country was covered with an immense ice-sheet, which moved south-west in its western parts, due south in the middle, and south-east in its eastern parts. The bottom moraine of this ice-sheet spreads over the country, and consists of a mixture of far-transported boulders with debris of the local rocks. It is the equivalent of the British Till and of the Swedish *Krossstensgrus*. It sometimes gets the local name of *Richk*. It rises into elongated hills or "drums," which extend also throughout the Government of Novgorod, and must be distinguished from the Åsar. These last, in the opinion of Prof. Schmidt, who indorses the explanation of A. Törnebohm, are shore-walls of those mighty sub-glacial rivers, so well described by Nordenskjöld, which circulate on the surface of the ice-sheets, and, after having found an exit through the ice, run beneath it.

During the first part of the Post-Glacial period the Gulf of Finland, and probably all the northern part of the Baltic Sea, formed an immense lake which subsequently was connected with the ocean, and received its brackish-water fauna. The level of this lake was about 60 feet higher than the present level of the Baltic. The presence of Baltic shells at greater heights in the north (the author of this notice found them at 124 feet, on

[1] Notes on the Proceedings of the International Polar Conference, held at Vienna, April 17-24, 1884. Read at the Royal Meteorological Society by Robert H. Scott, F.R.S., President.

[1] *Izvestia geologicheskago Komiteta*, vols. i. and ii. (fasc. 1 to 6), 1882 and 1883.—*Trudy geologicheskago Komiteta*, vol. i. fasc. 1; 4to. (St Petersburg, 1883.)

the northern coast of the Gulf of Finland, seven miles distant from the sea-shore) is explained by the increase of the rate of upheaval of the country towards the north. This old lake, like Lake Ladoga of our days, seems to have had but a poor fauna. Many smaller lakes which covered Esthonia, had a peculiar freshwater fauna. Gravel and sand, with *Ancylus fluviatilis*, like that found in Lake Baykal, and *Lymnæus ovatus*, as also *Neritina fluviatilis*, *Paludina impura*, *Unio*, and *Cyclas* are found at heights varying from 50 to 150 feet above the actual sea-level. On Œsel these deposits are widely spread, and descend to a level of 20 feet above the sea. At a still later period the lakes were filled with ooze, which constitutes now the so-called "marl of prairies" (*Wiesenmergel*) filled up with *Planorbis*, *Lymnæus*, &c., and containing also remains of man, together with bones of reindeer, as described by Prof. Grewingk.

In connection with this subject reference may be made to the conclusions arrived at as to the glacial formations by M. Nikitin, while making the geological survey within the limits of sheet 58 of the geological map of Russia, comprising Yaroslav and the eastern parts of Novgorod and Tver. The features of the Till, or Boulder-clay, which covers this region, are so much at variance with the theory of floating ice, which has been proposed to explain them, as well as with every other aqueous theory, and so much in conformity with the idea of a bottom moraine, that M. Nikitin has been compelled to admit the former extension of the northern ice-sheet of the Glacial period throughout the region of the Upper Volga (vol. ii. fasc. 3). The Boulder-clay of the Government of Poltava, sometimes 20 m thick, consists of triturated, unstratified materials, partly derived from sources within the region itself, and partly brought from the north. It contains scratched boulders, and though undoubtedly of glacial origin, its precise mode of formation still remains in dispute, notwithstanding the careful attention given to the study of the question by M. Armashevsky (vol. ii. fasc. 6).

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The Natural Sciences Tripos, Part I., commenced on May 17; Part II. will commence on May 29.

The examiners in the Mathematical Tripos of 1883-84 have reported that the work done in Part II. was on the whole disappointing, and inferior to that usually done in the old "five-days" examination. They suggest that this may be due to its taking place in the Easter Term, in which revision of subjects is usually much interrupted. In Part III. eleven candidates presented themselves, of whom seven were placed in the first division. The work was extremely good, the candidates having judiciously specialised their reading.

SCIENTIFIC SERIALS

Bulletin de l'Académie Royale de Belgique, February 2.—On the crepuscular phenomena of the months of November and December 1883, by F. Terby.—On the physiological action of aspidospermine (bark of *Aspidosperma quebracho*), by Dr. Closson.—Remarks on some Sanskrit verbal roots of the eighth class, by J. van den Gheyn.—Contributions to the biography of the portrait painter A. de Vries, and of the Flemish painter Theodore van Loon, by Auguste Castan.—Biographical notice of the Dutch painter Marin van Romerswael, by Henry Hymans.

March 1.—Note on the Pons-Brooks comet 1812, observed at Louvain during the winter of 1883-84, by F. Terby, and at Brussels by L. Niesten.—On an empirical relation between the coefficient of internal friction of liquids, and its variations under changes of temperature, by P. de Heen.—Preliminary communication on the anatomy of the Acarians, a group of Arachnidæ, by J. MacLeod.—On the changes of refrangibility in the electrical spectra of hydrogen and magnesium, by Ch. Fievez.

Journal of the Russian Chemical and Physical Society, vol. xvi. fasc. 1.—The dilatation of liquids, by D. Mendeléeff.—On the tension of vapour of solutions, by D. Konovaloff. The author has resorted in his measurements to a method much like that of Magnus, and gives the results of his measurements (illustrated by curves) for mixtures of water with alcohols and acids: formic, acetic, propionic, and butyric; they are followed by a discussion on the distillation of solutions, on mixtures, and on the solubility of liquids.—On an acoustic instrument for measuring the number of vibrations, by A. Izraïleff.—New demonstrations of the conditions of minimum of deviation of a ray by the prism, by K. Kraevitch. In most treatises on physics this demonstration is made by means of methods more or less artificial, excepting the treatise of Jamin, who has resorted to differential calculus. However long, M. Kraevitch's demonstration is very simple, and is deduced very naturally out of the fundamental laws of refraction.—On the friction of well lubricated bodies, by N. Petroff.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 8.—"On a Relation between the Coefficient of the Thomson Effect and certain other Physical Properties of Metals." By Shelford Bidwell, M.A., LL.B.

Having observed that the coefficient of the Thomson effect is generally positive in those metals which have a great specific resistance and specific heat, and negative in those which are distinguished by a great coefficient of expansion, the author endeavoured to find an empirical formula expressing the coefficient of the Thomson effect in terms of the specific resistance, specific heat, and coefficient of expansion. Though he was not altogether successful, he believes that the subjoined table points to a close relation between them.

I. Metals	II. Coefficient of Thomson effect.	III. $H \times R - E^2$	IV. Last column divided by 2400
Ni	5·12	12320	5·13
Fe	4·87	9918	4·13
Pd	3·59	7086	2·95
Pt (soft)	1·10	2309	0·96
Pt (hard)	0·75	—	—
Mg	0·95	1384	0·58
Pb	0	− 604	−0·25
Al	−0·39	1942	0·81
Sn	−0·55	− 868	−0·36
Cu	−0·95	−1137	−0·47
Au	−1·02	−1172	−0·49
Ag	−1·50	−2246	−0·94
Zn	−2·40	−2355	−0·98
Cd	−4·29	−4958	−2·07

The first column contains the names of the metals, except alloys, given in Tait's thermo-electric diagram (*Trans. R.S.E.*, vol. xxvii. p. 125). The second column gives the coefficients of the Thomson effect: these are taken from Everett's table ("Units and Physical Constants," p. 151), which is based upon Tait's diagram.

H, R, and E being numbers proportional to the specific heats, specific resistances, and coefficients of expansion of the various metals, $H \times R - E^2$ gives the numbers in the third column of the table. H = specific heat $\times 10^3$, R = specific resistance $\times 10^3$, E = coefficient of expansion $\times 10^8 \div 34$. The multipliers 10^3 and 10^8 were used merely for the convenience of getting rid of decimals; the divisor, 34, was so chosen that while the ratio of the first number to the last in Column III. should be as nearly as possible equal to the ratio of the first number to the last in Column II., the number corresponding to lead in Column III. should at the same time be as near zero as possible. Both conditions could not be exactly fulfilled at once. The authorities for the specific heats, specific resistances, and coefficients of expansion are given in the paper.

Column IV. gives the numbers in Column III. divided by 2400, to facilitate comparison with Column I.

It will be seen that with one exception the order of magnitude of the numbers in Column IV. is exactly the same as the order of those in Column II. The rate of decrease is not, however, the same, the numbers diminishing too rapidly in the upper half of Column IV., and too slowly in the lower half.[1]

[1] With regard to aluminium it is suggested that Matthiessen's determination of the specific resistance, 0·029, is possibly too high. Moreover the author found experimentally that the Thomson coefficient of the specimen of aluminium which he used was slightly + instead of −, as given in Column II.: it is also shown as + in the diagram at p. 178 of Jenkin's "Electricity." If its specific resistance were as high as 0·026, it would come between magnesium and lead in Column IV.

Geological Society, April 23.—Prof. T. G. Bonney, F.R.S., president, in the chair.—The following communications were read:—On the geology of the country traversed by the Canada Pacific Railway, from Lake Superior to the Rocky Mountains, by Principal J. W. Dawson, C.M.G., F.R.S. This paper recorded observations made by the author with reference to the geology of the North-West Territories of Canada, in an excursion in the summer of 1883, along the line of the Canada Pacific Railway as far as Calgary, at the eastern base of the Rocky Mountains. After referring to the labours of the Canadian Geological Survey, and more especially of Dr. G. M. Dawson, in this region, the author proceeded to notice the Laurentian, Huronian, and other pre-Silurian rocks of the west of Lake Superior and the country between that lake and the Red River. Good exposures of many of these rocks have been made in the railway-cuttings, and important gold-veins have been opened up. The Laurentian rocks present a remarkable uniformity of structure over all the vast territory extending from Labrador to the Winnipeg River, and where they reappear in the mountains of British Columbia. They are also similar to those of South America and of Europe; and there was on the table a collection of Laurentian rocks from Assouan, in Upper Egypt, made by the author in the past winter, which showed the reappearance of the same mineral characters there. In Egypt there is also an overlying crystalline series, corresponding in some respects with the Huronian. The Huronian rocks west of Lake Superior are, however, more crystalline than those of Lake Huron, and may be of greater age. The Palæozoic rocks are exposed in places on the western side of the old crystalline rocks near the Red River, and show a remarkable union and intermixture of Lower and Upper Silurian forms, or rather, perhaps, a transition from the one fauna to the other in a very limited thickness of beds. The collections of Mr. Panton, of Winnipeg, were referred to in this connection. The Cretaceous and Eocene beds of the plains were then noticed, and certain sections showing the coal-bearing series described; and comparisons were instituted between the Cretaceous and Eocene succession in Canada and that in the United States and elsewhere. The Pleistocene drift deposits constitute a conspicuous feature on the western prairies. Along the railway, Laurentian, Huronian, and Palæozoic boulders from the east may be seen all the way to the Rocky Mountains, near which they become mixed with stones from these mountains themselves. The vast amount of this drift from the east and north-east, and the great distance to which it has been carried, as well as the elevation above the sea, are very striking. The great belt of drift known as the Missouri Coteau is one of the most remarkable features of the region. It was described in some detail where crossed by the railway, and it was shown that it must represent the margin of an ice-laden sea, and not a land-moraine, and that its study has furnished a key to the explanation of the drift deposits of the plains, and of the so-called "Terminal Moraine," which has been traced by the geologists of the United States from the Coteau round the basin of the Great Lakes to the Atlantic.—On the Dyas (Permian) and Trias of Central Europe and the true divisional line of these two formations, by the Rev. A. Irving, B.Sc.

Zoological Society, May 6.—Prof. W. H. Flower, F.R.S., president, in the chair.—Prof. Bell exhibited some specimens of *Estheria melitensis* sent from Malta by Capt. Becher, R.A., and stated that, in answer to his inquiries, that gentleman had confirmed the fact of the males appearing to equal in number the females, as had been stated by previous observers of the members of the genus.—Mr. G. A. Boulenger read a paper on the reptiles and Batrachians of the Solomon Islands, principally based upon two collections forwarded to the British Museum from that locality by Mr. H. B. Guppy, R.N.—Lieut.-Col. Godwin-Austen, F.R.S., exhibited an old Indian drawing representing a tiger-hunt; and called attention to the colour of one of the elephants engaged, which was of a creamy white.—Prof. Flower, F.R.S., described the state of dentition of a young Capybara (*Hydrochœrus capybara*) born in the Society's Gardens, which had died when eight days old. All the teeth of the permanent series were present and in use.—Prof. F. Jeffrey Bell read a paper on *Amphicyclus*, a new genus of Dendroclinotous Holothurians, and its bearing on the classification of the suborder.—A communication was read from Mr. Edgar A. Smith, containing a report on the land and freshwater Mollusca which had been collected during the voyage of H.M.S. *Challenger* from December 1872 to May 1876. The collection contained examples of 152 species, some of which were of interest and several new to science.—A communication was read from Count Berlepsch and M. Taczanowski, containing an account of a second collection of birds made in Western Ecuador by Messrs. Stolzmann and Siemiradzki. There were stated to be examples of 177 species in this collection, which had been made at various localities on the western slope of the Cordilleras above Guayaquil. The following species were described as new:—*Henicorhina hilaris*, *Chlorospingus ochraceus*, and *Sphenopophila pauper*. A new genus, *Pseilotriccus*, was proposed for *Todirostrum ruficeps* of Kaup.—A paper by Messrs. Godman and Salvin was read, which contained a list of the Rhopalocera obtained by Mr. G. French Angas during a recent visit to the Island of Dominica. The number of species in this collection was twenty-seven, among them being a species of Nymphalinæ apparently new; this the authors proposed to describe as *Cymatogramma dominicana*.—Mr. Herbert Druce read a paper describing the Heterocera collected by Mr. Angas on the same island.

Victoria Institute, May 6.—Vice-Chancellor Dawson, C.M.G., of McGill University, Montreal, read a paper on prehistoric man in Egypt and Syria, and described the investigations which he had carried on during the winter in Egypt and Syria. Dr. Dawson illustrated his paper by diagrams and specimens, among which were several of the bones of animals, in the classification of which Prof. Boyd Dawkins, F.R.S., had taken part; in dealing with his subject Dr. Dawson remarked that great interest attaches to any remains which, in countries historically so old, may indicate the residence of man before the dawn of history. In Egypt, nodules of flint are very abundant in the Eocene limestones, and, where these have been wasted away, remain on the surface. In many places there is good evidence that the flint thus to be found everywhere has been used for the manufacture of flakes, knives, and other implements. These, as is well known, were used for many purposes by the ancient Egyptians, and in modern times gun-flints and strike-lights still continue to be made. The debris of worked flints found on the surface is thus of little value as an indication of any any flint-folk preceding the old Egyptians. It would be otherwise if flint implements could be found in the older gravels of the country. Some of these are of Pleistocene age, and belong to a period of partial submergence of the Nile Valley. Flint implements had been alleged to be found in these gravels, but there seemed to be no good evidence to prove that they are other than the chips broken by mechanical violence in the removal of the gravel by torrential action. In the Lebanon, numerous caverns exist. These were divided into two classes, with reference to their origin, some being water-caves or tunnels of subterranean rivers, others sea-caves, excavated by the waves when the country was at a lower level than at present. Both kinds have been occupied by man, and some of them undoubtedly at a time anterior to the Phœnician occupation of the country, and even at a time when the animal inhabitants and geographical features of the region were different from those of the present day. They were thus of various ages, ranging from the post-Glacial or Antediluvian period to the time of the Phœnician occupation. In illustration of this, the caverns at the Pass of Nahr-el-Kelb and at Ant Elias were described in some detail, and also, in connection with these, the occurrence of flint implements on the surface of modern sandstones at the Cape or Ras near Beyrout. These last were probably of much less antiquity than those of the more ancient caverns.

SYDNEY

Linnean Society of New South Wales, March 26.—C. S. Wilkinson, F.G.S., F.L.S., president, in the chair.—The following papers were read:—On plants which have become naturalised in New South Wales, by the Rev. W. Woolls, Ph.D., F.L.S. In this paper the author not only deals with the various importations, whether intentional or otherwise, of new and often injurious weeds, but also with the general and deliberate destruction of the native flora, especially in timber. He also points out that many of our most valuable trees, as for instance the Myall (*Acacia pendula*), are dying out in consequence of the want of any kind of protection for the young plants. They are produced in abundance, but eaten down as fast as they grow. The paper contains a complete account of all the exotic *Mono-* and *Di-cotyledons* known in the colony.—The Australian *Hydromedusæ*, part i., by R. von Lendenfeld, Ph.D. It is proposed in this paper to describe a series of new species of *Hydromedusæ* of our shores. A new classification of the *Hydromedusæ* is proposed. The present paper forms a

Prodromus of a system of the *Hydroid Zoophytes* and *Craspedote Medusæ*, which will be used and marked out in detail in subsequent papers. The order of the *Hydromedusæ* is here divided into five sub-orders and twenty-one families.—The *Scyphomedusæ* of the Southern Sea, part ii., by R. von Lendenfeld, Ph.D. This paper is a continuation of the paper read at the last meeting of the Society, and contains a description of all the species of the third order of the *Scyphomedusæ*, the *Cubomedusæ*, which have been described from the South Sea.—On some fossil plants from Dubbo, New South Wales, by the Rev. J. Milne Curran, F.G.S. This paper, which was illustrated by specimens in an extraordinary state of preservation, and mounted for the microscope, is a very careful essay towards the determination of the (so-called) Hawkesbury beds at Dubbo, and names or describes as belonging to that formation the following forms, viz. :—*Sphenopteris crebra*, *S. glossophylla*, *Neuropteris australis*, *Thinfeldia odontopteroides*, *T. media*, *Alethopteris Currani*, *A. concinna*, *Merianopteris major*, and a Conifer, *Walchia milneana*. Of new species Mr. Curran names *Odontopteris macrophylla*, *Alethopteris* (*Pecopteris*) *australis*, *Hymenophyllipes dubia*, *Podozamites*, sp., and one Conifer set down doubtfully as *Walchia piniformis*.

BERLIN

Physiological Society, April 18.—Prof. Zuntz, with the help of a diagram, described and explained an apparatus for determining the gaseous inhalation and exhalation in the case of animals affected with curare. Essentially it consisted of two glass bells set by means of an electric motor into regular up-and-down rhythmical movements, alternately sinking into a larger vessel filled with mercury, and rising out of it. Each bell had two connecting-tubes, one communicating with the animal under examination, the other with other parts of the apparatus. One bell was connected with a graduated reservoir containing the air that was to be inhaled, while the second communicated with a bell, likewise graduated and filled with mercury, intended to receive the exhaled air. By means of inserted mercurial valves the path of air was so arranged that in the rising of the bells the first came into communication only with the reservoir, and filled itself with the contents of the same, while the second bell had communication solely with the trachea of the animal, and drew in the air of the lungs. In the sinking of the bells, on the other hand, the first communicated with the trachea, and forced the air that was to be breathed into the lungs, while the second communicated with the reservoir, and emptied into it the air previously exhaled from the lungs. This apparatus kept up the most regular artificial respiration in animals paralysed by curare for any length of time, even for many hours, and enabled, on the one hand, gases that might be exactly measured, and of any composition that might be desired, to be employed for the purpose of respiration; on the other, the products that were exhaled to be collected for measurement and chemical analysis. A whole series of other arrangements connected with this respiratory apparatus, provided automatically for supplying the reservoir with exactly the appointed kind of air and in uniformly identical mixture, as also for producing and conducting to the reservoir, automatically, the requisite quantities of oxygen for determinate experiments.—Dr. Kempner, with the apparatus above described, had, in the laboratory of Prof. Zuntz, instituted measuring experiments on the influence of the proportion of oxygen in the air that was to be inhaled on the consumption of oxygen and the exhalation of carbonic acid from the lungs. It was a universally accepted doctrine that the proportion of oxygen in the air to be inhaled might vary within very wide limits, from between 100 and 15 per cent., without essentially affecting the respiration, and that only when the oxygen sank to 5 per cent. or less did phenomena of suffocation appear. This view, which was based principally on the experiments of Regnault and Reiset, was not, in Dr. Kempner's opinion, sufficiently justified by the experiments referred to. In consequence he some years ago carried out experiments on himself by inhaling, for the space of ten minutes on each occasion, by means of forced inspiration, air of different proportions of oxygen, and then analysing the exhaled air. From these experiments he found that respiration and the consumption of oxygen were not influenced by a higher than the normal proportion of oxygen in the air that was breathed. With a reduction, however, of the oxygen in the air to be inhaled below the normal proportion, the consumption of oxygen became likewise reduced. It might be supposed that this result, which was at variance with the general view on the subject, was due to the abnormal conditions of respiration and the forced inspiration. It was necessary, therefore, that this result should be confirmed by experiments on animals. Such, accordingly, were soon afterwards carried out by Dr. Kempner, and yielded a result similar to that arrived at in the experiments on men. Seeing, however, that the movements of the animal might have affected the result, Dr. Kempner determined on repeating the examination with animals that had been subjected to curare. The experiments were carried out on animals with the respiratory apparatus of Prof. Zuntz. After fasting for twenty-four hours, the animals were kept, throughout the time that the experiments lasted, in exactly the same temperature—which was a warm one—and they made thirty artificial respirations per minute. The result yielded by these last experiments was that with a higher than the normal proportion of oxygen in the air breathed the consumption of oxygen was not different from that in the case of normal air. When, however, the proportion of oxygen sank to 18 per cent., the consumption of oxygen became diminished, and decreased still further in proportion as the oxygen of the air was further lessened. Similarly the amount of carbonic acid exhaled was affected by the reduced proportion of oxygen in the inspired air. Carbonic acid also decreased with the decrease of oxygen, though not in the same degree as did the consumption of oxygen, a circumstance which pointed to the fact that in the exhaled carbonic acid was contained a certain portion of this gas formed by processes of dissociation independently of the oxygen of the inhaled air. An explanation of this fact, of such high importance physiologically, that a reduced proportion of oxygen in the air inhaled was attended by a reduced consumption of oxygen, was next given by the speaker, and in conclusion he indicated a series of practical useful applications which might be made of the fact.

THE DILUTION OF DOG POISON

M. PASTEUR has communicated to the French Academy of Sciences (May 19, 1884) the results of his experiments on the attenuation of the virus of rabies, which, if they should be confirmed, would furnish us with the means of protecting dogs from rabies, and as a necessary sequel of protecting the human race from hydrophobia, that absolutely deadly and intractable disease which in every country where rabies exists devours every year some hundreds of human victims.

Starting from the idea, now well established for at least some of the infectious maladies, viz. that the virus of a particular disease of this class on its passage through different species of animals is subject to alteration of its virulence, M. Pasteur inoculated monkeys with the virus taken from a dog affected with rabies, and found that it thereby became considerably altered. This alteration consists in a decrease of intensity, and it is the more marked the greater the number of removes. After the third remove (*i.e.* after having passed successively through three monkeys) it becomes attenuated to such a degree that inoculation with it of dogs, rabbits, and guinea-pigs does not produce fatal rabies. Dogs so inoculated remain protected against further virulent poison such as is derived from a rabid dog.

But on the other hand the virus of rabies on its passage through the rabbit and guinea-pig increases in virulence, its intensity becoming even greater than that of the virus taken from a dog, rabid in the usual way (*rage des rues*). The maximum increase in intensity is not, however, attained until several transmissions through the rabbit or guinea-pig.

In this way it is possible to produce virus of various degrees of intensity, from the weakest, *i.e.* virus taken from the rabid dog and passed successively through several monkeys, to the strongest, *i.e.* virus passed successively through several rabbits or guinea-pigs.

M. Pasteur states that he has succeeded, by inoculation of the blood of rabid animals, in devising a simple method of obtaining attenuation of the virus, and of herewith protecting dogs from fatal rabies, but the experiments not being yet completed do not permit of a detailed description.

Without wishing to say anything derogatory as regards these remarkable results, it is greatly to be regretted that M. Pasteur, not being himself a pathologist, has not availed himself of the aid of his medical colleagues, in order to definitely ascertain whether the disease which he produced by inoculation in the dog, monkey, rabbit, and guinea-pig—for this seems to be at the root of his statements—was really rabies. However, he has asked and obtained from the French Minister of Public Instruction a Commission which is to compare the results of the inoculation, from a rabid dog, of twenty dogs, previously treated by M. Pasteur with his attenuated virus, with those of the inoculation of twenty other dogs not previously "vaccinated."

This Commission, comprising such acknowledged authorities in physiology and pathology as M. Béclard, M. Paul Bert, M. Bouley, Dr. Villemin, and Dr. Vulpian, will no doubt soon be able to decide this question one way or the other, and its judgment will be awaited by all medical men as well as by the general public with anything but indifference.

The experiments of M. Pasteur, published in the *Comptes Rendus* of the Academy of Sciences for May 19, are these :—

I. "If rabies is transmitted from the dog to the monkey, and further, from monkey to monkey, the virulence of the virus becomes weakened on each transmission. The virus, having become diminished in virulence by these transmissions from monkey to monkey, if reintroduced into the dog, rabbit, or guinea-pig, maintains its attenuated character. In other words, the virulence does not return at a bound to the virulence of the virus of a dog affected with rabies of the usual kind, *i.e.* produced by the bite of a dog (*à rage des rues*).

"Under these conditions the attenuation can easily be accomplished by a small number of transmissions from monkey to monkey, to such a point that it does not produce rabies in the dog by hypodermic inoculation. Even inoculation by trephining, an infallible method to communicate rabies, cannot produce any result ; it creates nevertheless a refractory condition of the animal against rabies.

II. "The virulence of the rabid virus increases on its passage from rabbit to rabbit, and from guinea-pig to guinea-pig. When in this way the virulence has reached its maximum in the rabbit, it can be transmitted in this state to the dog, and it shows here a much greater intensity than the virus obtained from a dog affected with rabies in the usual manner (*rage des rues*). This virulence is of such an intensity that after inoculation into the blood of a dog it invariably produces fatal rabies.

III. "Although the virulence increases on the passage of the virus from rabbit to rabbit, or from guinea-pig to guinea-pig, it requires several successive transmissions through these animals to attain its maximum, having previously become attenuated by its passage through the monkey. Similarly the virulence of the ordinary rabies of the dog, which, as we have just shown, is not by any means the greatest that the rabid virus is capable of attaining, requires several successive transmissions through the rabbit in order to attain its maximum.

"It follows from the experiments just described that we can easily render dogs proof against rabies. It is readily understood that the experimenter can at will procure rabid virus attenuated in various degrees : some, non-fatal, protecting the animal from the effect of more active as well as of fatal virus.

"The following example illustrates this :—Extract by trephining from a rabbit dead of rabies after an incubation prolonged by several days beyond the shortest period of incubation in the rabbit. This latter is generally comprised within seven to eight days after inoculation, by trephining, with the most intensive virus. From the above rabbit, *i.e.* the one with the prolonged incubation, virus is taken and inoculated, always by trephining, into a second rabbit ; from this again virus is taken and inoculated into a third rabbit. Each of these different samples

of virus, increasing in strength on every transmission, is at the same time inoculated into a dog. This latter will then be found capable of resisting the most fatal virus, having become completely refractory to rabies, no matter whether the virus, derived from a case of common rabies (*rage des rues*), is introduced by intravenous inoculation or by trephining."

THE MAMMALIA OF INDIA AND CEYLON

Natural History of the Mammalia of India and Ceylon. By Robert A. Sterndale, F.R.G.S., F.Z.S. (Calcutta: Thacker, Spink, and Co.; London: Thacker and Co., 1884.)

THIS book may fairly be described as an attempt by an unscientific writer to compile a scientific work. The author is favourably known as a describer of Indian wild sports, and his observations on the habits of animals are generally good and often original. His best known publication, "Seonee or Camp Life in the Satpura Range," although not quite equal to Forsyth's delightful "Highlands of Central India," rises above the level of ordinary Indian sporting works. In the volume now published he has attempted the somewhat ambitious task of compiling a popular manual of Indian mammalia, comprising not only those described in Jerdon's "Mammals of India" (which is restricted to the kinds found in the Indian Peninsula and the Himalayas), but also the species living in Assam, Burmah, Ceylon, and "the countries bordering the British Indian Empire on the north." By including some (not all) of the mammals described by A. Milne-Edwards from Eastern Tibet, several of those recorded by various authors from Kashgaria, Afghanistan, and Persia, and some Malay types, the total number of species enumerated is brought up to 482. This number, however, is partly made up by nominal species, the writer having compiled his lists from various authorities of unequal value.

Had Mr. Sterndale confined his descriptions to the larger and better known mammals of India and the surrounding countries, he might possibly have achieved greater success. He has bestowed much labour upon the book, and has in some cases, but unfortunately not in all, had recourse to good and recent information. Thus he adopts Flower's and Mivart's classification of the *Carnivora*, and Alston's arrangement of the rodents, whilst he places the dugong in the *Cetacea*, and *Galeopithecus* amongst the lemurs.

The actual descriptions of species are for the most part taken from other writers, and the same may be said of localities, which, however, are not always correct, even in the case of the larger and better known animals. Thus the markhor (*Capra falconeri* v. *megaceros*) is said to be found in Ladakh, where it does not occur, although common in Astor and Gilgit, and the hog-deer, *Axis porcinus*, is stated to exist "throughout India, though scarce in the central parts," whereas it is not known with certainty to inhabit any part of the peninsula of India except the plains of the Ganges and Indus. Many other instances might be quoted. Mr. Sterndale is not even aware that *Tragulus kanchil* exists in Tenasserim, although its occurrence there was well known to Blyth, at least twenty-five years ago. He is unaware also that *Canis lupus* has been obtained in Gilgit, and *Nectogale elegans* in Sikkim. But although *Tragulus kanchil* does not receive a number and separate notice as one of the Indian mammalia, *Mustela nudipes*, a purely Malay insular type, not recorded from continental Asia, is included in the list as No. 190, with the remark that "this species may be discovered in Tenasserim." There is a want of system in the admission and exclusion of species throughout. Thus *Macacus thibetanus* (No. 23) and *Nemorhædus edwardsii* (No. 453) are described, whilst *Semnopithecus roxellana*, *Elaphodus cephalophus*, and *Cervulus lachrymans* are ignored, although all are from the same country in Eastern Tibet, and described in the same work by one author. Similarly whilst some Andaman and Nicobar bats, *e.g.* *Rhinolophus andamanensis* (No. 48) and *Phyllorhina nicobarensis* (No. 63) are included, no mention is made of four *Megacheiroptera* from the same islands, viz. *Pteropus nicobaricus*, *Cynopterus brachyotus*, *C. scherzeri*, and *C. brachysoma.*

As might be anticipated, the micro-mammalia are not treated in a manner that will afford much aid to a student. The writer is unacquainted with Mr. Oldfield Thomas's important paper on the rats and mice, and with Mr. Dobson's work on the *Insectivora*. The account of the latter order and of the *Rodentia* is full of errors. The mistakes in the case of the bats are even less excusable, for Dobson's catalogue is quoted, and, to some extent, followed. Had Mr. Sterndale simply taken all his names, descriptions, and localities from Dobson he would have been safe. But he appears to have found a difficulty in making the names and the arrangement in Jerdon's "Mammals" fit into Dobson's scheme, and he has adopted a compromise, with the result that, besides repeating several mistakes of Jerdon's, he has added not a few of his own. Thus, to take a few examples, he gives as two distinct species No. 54, *Hipposideros armiger*, and No. 64, *Phyllorhina armigera*, although he notices that *Hipposideros* and *Phyllorhina* are the same genus. He quotes as distinct species No. 92, *Scotophilus fuliginosus*, and No. 119, *Miniopterus schreibersii*, shown by Dobson to be identical. Similarly No. 58, *Hipposideros larvatus*, is the same as No. 59, *H. vulgaris*. But perhaps the most characteristic instance of error is in the last species in the order No. 121, *Nyctophilus geoffroyi*. This is taken from Jerdon, and no trace of it is said to be found "in Dobson's monograph, which is so exhaustive as far as Asiatic species are concerned." As the bat in question (*N. timoriensis*) is peculiar to the Australian region, it is naturally omitted in Dobson's "Monograph of Asiatic *Chiroptera*," but it is included in his General (British Museum) "Catalogue of Chiroptera." Jerdon's mistake in classing the species as Indian was founded on what looks very like a printer's error in Blyth's "Catalogue of Mammalia in the Museum of the Asiatic Society."

These details will show the character of the work: mistakes such as those enumerated are to be found throughout. At least a dozen omissions have been noted besides those already mentioned. The book is well printed and illustrated, and many details of osteology, &c., described and figured, so that it is important to show why, despite its merits, it falls far short of what is required in an exhaustive account of Indian mammalia.

There are two portions of the work of which it is possible to speak in terms of high praise. First, wherever

the habits of animals are recorded on personal observation they have evidently been accurately and carefully noted. The author is a genuine naturalist with a thorough love and admiration for animals, and in consequence he possesses considerable power of understanding and appreciating them. Secondly, the woodcuts are numerous and for the most part excellent. A few, such as the big-headed Gaur (*Bos gaurus*) on p. 530 and the musk-deer on p. 493 are less successful, and it may be questioned whether a nylgao can stretch itself into the gallop depicted at p. 477, but the spirit of the cut last-named would atone for a worse fault, and there is far more ground for admiration than for criticism. As an amusing work, with good illustrations, to which residents in India may have recourse for the identification of the principal mammals, this volume will probably find a ready place in the Anglo-Indian library. For the determination of the smaller kinds, and for a knowledge of the less known and more difficult species, the student will do well to search elsewhere.

W. T. B.

NORTH AMERICAN MOLLUSCA

A Review of the Non-Marine Fossil Mollusca of North America. By Charles A. White. (Washington: Government Printing Office, 1883.)

THE Hon. J. W. Powell, the Director of the Geological Survey in the United States, continues his valuable contributions to scientific knowledge by the publication of his annual reports; and the volume which is now before us forms part of the Report for 1881-82.

This volume contains 144 pages, besides a full index, and thirty-two lithographic plates. It is carefully and modestly written, and the author candidly admits that our knowledge of the subject treated by him is "very imperfect." The title of the work may be open to a slight criticism; and the word "inland" ("*binnen*" in German) might be preferable to the negative expression "non-marine," which is used by the author.

The geological formations which are embraced in the "Review" are the Devonian, Carboniferous, Jurassic, Triassic, Cretaceous, Laramie, and Tertiary. With respect to the Laramie formation, the author regards the group as occupying a transitional position between the Cretaceous and Tertiary; it is remarkably fossiliferous, inasmuch as a greater number of the species mentioned in the "Review" come from that group than from any other. The total number of North American non-marine or inland fossil species and well-marked varieties appears to be 227, of which 141 are found in the Laramie formation or group. Twelve species are Palæozoic, and of these no fewer than seven species belong to the Pulmonibranchiata, and to the families *Limacidæ* and *Helicidæ*, which are not only terrestrial mollusca, but undoubtedly air-breathers. *Strophites grandæva* of Dawson, from the Devonian formation, is by far the most ancient land shell hitherto known to us. In the face of these facts and in the absence of any facts to warrant the conclusion of the author, how can we reasonably agree with him "that molluscan life began in the sea, and that all fresh-water and land mollusca have been primarily derived from those of marine origin"? Although no land mollusk has yet been discovered in the oldest fossiliferous formation, it is evident that land and consequently terrestrial conditions must then and long previously have existed, so as to account for the sedimentary strata of which that formation consisted and for the prevalence of *Lingula* and other shallow-water Brachiopoda in the Silurian epoch.

It is curious to notice that so many species of what are usually considered marine Conchifera (*Ostrea, Anomia,* and *Mytilus*) occur in the Laramie group, and one of *Anomia* in the Cretaceous formation. This confirms the experiments of Beudant and other naturalists, that many marine gill-bearing mollusks can live either in their own native and proper element or can gradually become accustomed to a brackish and ultimately a fresh-water habitat. The author also notes the "persistence through long periods of geological time of even the simpler types of non-marine mollusks, after they were once established." And he remarks with respect to the Gastropoda that, "although in geological rank the Gasteropoda are so much in advance of the Conchifera, the various families of the former seem to have been developed as early in geological time as those of the latter, and so far as we are now acquainted with the history of the fossil non-marine mollusca of North America, it appears that highly-organised land pulmonate Gasteropods were introduced quite as early as any of the Conchifers. Indeed from present indications we are led to believe that the relations of the different classes of non-marine mollusca to each other were much the same in all geological epochs as they are to-day." The following is also interesting:—"Notwithstanding the annual migration of myriads of aquatic birds between the northern and southern provinces of North America at the present time, and doubtless also ever since it has been a continent, the fresh-water molluscan fauna of those regions respectively are still distinct."

A few minor points of classification which are met with in the present work will not be accepted by conchologists without some hesitation, *e.g.* the extension of the so-called family *Rissoidæ* (or more properly *Littorinidæ*) so as to include the genera *Hydrobia* and *Bythinella*, which latter is a subgenus of *Bythinia* and belongs to the *Paludinidæ*. The families *Pisidiidæ, Physidæ, Ancylidæ, Vitrinidæ, Arionidæ, Pupidæ, Succinidæ,* and *Viviparidæ* seem to be also superfluous. In every well-organised army there ought to be a due proportion of men to officers of different ranks.

J. GWYN JEFFREYS

OUR BOOK SHELF

Plant-Life. By Edward Step. Third Edition. (London: T. Fisher Unwin, 1884.)

THIS is another attempt to give a popular description of some of the more sensational parts of the science of botany; though the plan is disconnected, the general idea of the book would not be bad, provided it were well carried out. It is to be regretted that the author has failed to realise that it is necessary to be accurate in popular description. For instance, it is gravely stated in italics that roots are never green (p. 29); we also read that *Ruscus aculeatus* "presents the remarkable appearance of a flower growing in the centre of a leaf" (p. 94), that the Cryptogams have no embryo (p. 211), and that the *Ricciaceæ* and *Characeæ* have stomata (p. 212)! On p. 171 he mistakes intercellular spaces for cells in *Isoëtes*, which he classes under the *Marsiliaceæ* (spelt *Marcileaceæ*, p. 212); and on p. 165 we are informed that the elaters

of *Equisetum* are composed of cells. As is usual in works such as this, the terminology of the reproductive organs of the lower forms is very erratic: thus he uses the terms "spore" and "antheridium" as equivalent in *Selaginella* (p. 139), he calls the "sporogonia" of the Mosses "sporangia," and the "oogonia" of *Fucus* "perispores."

On the subject of the lichen-gonidia theory he waxes warm, stating (p. 150) that it has been "termed sensational romance by every well-known practical fungologist and lichenologist." Of course every one is free to express his own opinion, but few who are not blind partisans will be prepared to agree with Mr. Step in excluding such men as De Bary, Schwendener, and Stahl from the list of "well-known practical fungologists and algologists."

Till so-called popular books are written with more accuracy, we should strongly advise those who wish to dabble in science either to abstain, or, better, to brace their minds to attack some text-book which can be depended upon: after this, if they wish, they can easily supply for themselves that cheap sentiment with which "Plant-Life" abounds.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Equatorial Coudé of the Paris Observatory

It was only on the 7th of this month that my attention was called to a letter in Nature (p. 4) from M. Lœwy, headed "Reply to Mr. Grubb's Criticisms on the Equatorial *Coudé* of the Paris Observatory." I deferred answering this letter as I was travelling at the time, and had not the necessary data by me to refer to; further, because I desired to see the second part of M. Lœwy's letter before making my reply; and lastly, because I hoped that some of the errors in M. Lœwy's first letter were misprints, and that he would have corrected them in his second.

I may observe in passing that the paper to which M. Lœwy alludes is a description of an instrument in the construction of which I am at present engaged, and that any criticisms of the equatorial *coudé* which it contained were merely incidental.

M. Lœwy assumes that my instrument is a modification of one which he described in 1871 in the *Comptes Rendus*. This description I have, as it happens, never seen, nor am I much concerned to defend myself from the suggestion of plagiarism, since the fundamental principle of what I have called the "siderostatic telescope" is one the advantages of which were recognised long before 1871, although mechanical difficulties prevented its application.

I find some difficulty in rendering my reply intelligible to your readers, for although the equatorial *coudé* has been described and figured in Nature, they are not as yet familiar with the form of the instrument which I am at present constructing. I now proceed to consider M. Lœwy's first letter.

I cannot admit that M. Lœwy's recital of what he is pleased to call my criticisms is accurate. He says:—

"To give weight to his argument Mr. Grubb examines a case of the construction of an instrument of 27 inches aperture, and he anticipates in the construction the following difficulties which he considers insurmountable:—(1) The optical difficulty of constructing a large plane mirror. (2) The practical difficulty of procuring a disk of the necessary dimensions. Mr. Grubb affirms there is no glass-works capable of making a disk of glass so large. (3) The difficulty of moving a mirror of which the weight, according to Mr. Grubb's calculations, will be very nearly half a ton. (4) The dearness of the instrument, which would cost more than an ordinary equatorial plus dome and observatory."

With regard to (1) I may remind M. Lœwy that I distinctly admitted the "*possibility*" of constructing such a mirror, but I expressed the opinion that inasmuch as no mirror of this size had yet been attempted success was problematical.

I now learn from M. Lœwy that such a mirror has been made, and that it "leaves absolutely nothing to be desired"; but he has not told us to what tests this mirror has been subjected. I am not aware that there exists in Paris an object-glass of sufficient size to embrace the whole pencil of light reflected from it, and without this it is not possible, in my opinion, to apply tests which can be legitimately considered final.

(2) I did say that *I believed* it to be impossible to obtain disks of such large dimensions, and I founded my belief on the fact that not many years ago I applied to several of the principal glass manufacturers of England, France, and Germany for prices of disks for mirrors, the weight of which would have been less than those mentioned by M. Lœwy, and none were willing to undertake the work. I am glad, however, to learn from M. Lœwy that the glass manufacturers are now prepared to furnish disks of such a size.

(3) The next difficulty M. Lœwy attributes to me is "the difficulty of moving a mirror of which the weight, according to Mr. Grubb's calculations, will be very nearly half a ton," and this, he says, "*has arisen from some error in calculation.*"

I would ask M. Lœwy to point out where I said anything of the difficulty of moving a mirror of half a ton weight. As I had a considerable share in the construction of the Melbourne mirrors, which weighed nearly four times this, it is hardly likely that I would assert such an absurdity; and as to the allegation of a wrong calculation, I ask M. Lœwy to point out the mistake he refers to, and in order to give him every facility for so doing I append it below. It is necessary first, however, to settle the matter of thickness.

M. Lœwy, in Nature, May 1 (p. 5), says:—"I have never said that the thickness should be 0·18 of the diameter. I have given 0·18 as a *maximum*."

I have, however, before me a paper presented by M. Lœwy to the Academy of Sciences, March 19, 1883, in which occurs the following passage:—"Mes recherches m'ont démontré que pour prévenir dans un miroir toute déformation causée par la flexion ou un léger *serrage*, il faut que l'épaisseur du verre soit de 0·18 du diamètre." Now if I understand this rightly, it means that he has found 0·18 of the diameter to be the *minimum* thickness necessary, and in no part of that paper does he speak of 0·18 as a *maximum*. He mentions in the following paragraph that a thickness of one-fourth is necessary under certain conditions; and further on in the same paper he says:—"C'est dans ces conditions que les miroirs du nouvel instrument ont été construits." This being so, I still think I was justified in assuming 0·225, a mean between one-fifth and one-fourth, as that which he recommended. Now as to diameter. He assumes a diameter of 38 inches to be sufficient for a 27-inch objective, but $27 \times \sqrt{2} = 38{\cdot}178$. Even this would only give full aperture of objective for the central pencil. For a moderate field nearly $38\frac{1}{2}$ would be in actual use.

Again, no optician in practice thinks of making a mirror without some margin; in small sizes one-fourth to one-half of an inch, but in such a size as this three-fourths of an inch all round is not an extravagant allowance, and therefore in adopting 40 inches diameter I did not exaggerate.

I therefore had as my data—

Diameter 40 inches.
Thickness $40 \times 0{\cdot}225 = 9$ inches.

The calculation then is simple.

$$\text{Solid contents in cubic feet} = \frac{\text{Area of 40 inch circle} \times 9}{1728}$$
$$= 6{\cdot}547 \text{ cubic feet};$$

and, taking a specific gravity of 2·5, each cubic foot would weigh $156\frac{1}{4}$ lbs.; therefore the weight of mirror $= 6{\cdot}547 \times 156{\cdot}25 = 1023$ lbs., or *rather more than* 9 *cwt*. I said nearly half a ton.

I may add that the specific gravity of the glass supplied to me by Messrs. Chance is rather more, viz. 2·52, which would give a higher result.

In another place M. Lœwy represents me as finding that "the mirror necessary for an equatorial *coudé* of 27 inches would weigh $8\frac{1}{4}$ tons"!!

I never made such a statement, and I challenge M. Lœwy to say what grounds he has for this assertion.

This is the second case in which he attributes to me statements which I have not made. A third and a fourth we shall come to just now. Your readers will remark that M. Lœwy (except in one minor instance) never quotes my words. Hence perhaps have arisen the serious mistakes into which he has fallen. Respecting the matter of thickness, M. Lœwy appears to have

altered his opinion since he presented his paper on March 19, 1883, to the Academy of Sciences; but, as I have shown, *he did make the statement he now repudiates;* and even if the result of my calculations, founded upon that statement, do not agree with what he now considers to be necessary, he has no right to attribute the discrepancy to any error of mine.

M. Lœwy then proceeds to show that it *is* possible to attach a weight of three-quarters of a ton to end of cross tube. This, I need hardly say, I never disputed; what I did say was, "The absurdity of hanging this three-quarters of a ton" (*i.e.* weight of mirror, objective, and all their supports and attachments) "on end of cross tube, *and yet calling the instrument one of precision*, is too apparent to need demonstration." If I were asked if it would be possible to hang three-quarters of a ton on each end of the Greenwich transit, I might be able to reply in the affirmative, but if I were asked to guarantee that the instrument would, under its new conditions, be as perfect an instrument of precision as it is in its present state, I would not be inclined to risk my "*reputation*" by any such guarantee, and yet M. Lœwy compares the equatorial *coudé* to a transit instrument in stability.

Lastly, on the question of expense. M. Lœwy is anxious to know where I obtained my information, but as I am content to accept his own figures (see his letter in your issue of May 1), so far as the equatorial *coudé* is concerned, there is no occasion to discuss this point. I take the 12-inch size, as it is the nearest to the only one completed, and most likely to be accurate. A 12-inch equatorial *coudé* is estimated at 44,000 francs, *i.e.* say 1760*l.*

Now, in estimating the relative costs of the two forms, your readers will agree with me that for our purposes the fair comparison is between the equatorial *coudé* and such equatorials as are most generally in use in this country, and it is well known that for 1760*l.* a first-rate 12-inch equatorial and dome can be procured, and *this is as nearly as possible what I said*, and I have to thank M. Lœwy for furnishing me with materials to prove my case with so little trouble.

My paper at the Royal Dublin Society (so far as concerned the equatorial *coudé*) was mainly confined to showing that in consequence of its complication it presented many difficulties in its manufacture, particularly for large sizes, and I considered (as I do still consider) that too much was sacrificed in endeavouring to make it an instrument of precision, and to obtain universality. The very fact of its being difficult to construct renders any success the more creditable, and I gladly take this opportunity of expressing my admiration for the excellence of the optical work of the Messrs. Henri, which appears to have withstood the enormous strain put upon it by the peculiarity of construction of the instrument. I still consider, and in this opinion I am joined by the several astronomers of eminence to whom I have spoken on the subject, that the good results are due to the excellence of the optical work, and have been obtained in spite of, and not by reason of, the peculiar form of the instrument.

And now I would say a few words generally on the comparison which has been instituted between the two forms. The claims of the instrument which I propose are very modest. I simply claim for it that by its peculiar construction I can obtain an instrument of large aperture at about one-fourth the usual cost, and that the observer can be situated in a most comfortable position, and free from all the various inconveniences of ordinary observing. I do not claim that the instrument will be one of precision, or that the images will be better after reflection from the mirrors, or that it will be universal, or that it will do all and everything which the equatorial *coudé* will do at four times the cost. What the equatorial *coudé* claims your readers already know. Like many other matters, this also will probably resolve itself into one of cost. If a director of an observatory has 1760*l.* at his disposal, it is for him to decide whether he will have a 12-inch equatorial *coudé*, which commands the whole visible heavens, or a 24-inch telescope on my plan, sacrificing in this case about 20° near the Pole; or, putting it another way, he may consider the question whether he will spend 1760*l.* on a 12-inch equatorial *coudé* or 500*l.* on one of my form of same aperture.

On this matter I shall have more to say in my second letter, in which also I propose to answer all the various objections M. Lœwy has raised to my form. It may, however, be interesting for him to learn that, with a single unimportant exception, he has not raised an objection which has not already been discussed and provided for in the new instrument; but he has suggested to me another objection to the equatorial *coudé* which I shall also treat of in that letter. HOWARD GRUBB

Rathmines, Dublin, May 19

The Earthquake

MY yacht, the *Glimpse*, lay on the ground in the River Colne at East Donyland, about half a mile above Wivenhoe, and as soon as I was able I joined her in order to study the effects of the late earthquake. I remained in the district about a fortnight, and examined the greater part of the focus of disturbance, over an area of about eight miles long by six broad. I distinguished on the ordnance map by appropriate marks (1) those places where the shock had been so violent that not only nearly all the chimneys had been knocked down but a large proportion of the house walls cracked and some boundary walls thrown down; (2) those where it had been less violent, many of the chimneys having been thrown down, but few or no houses cracked; and (3) those where it had been only sufficiently violent to throw down a few isolated chimneys. This third district extends in some directions much beyond the part examined. District No. 2 may be said to trend from Wivenhoe south-west to somewhat south of Little Wigborough, but sends a small, narrow branch north-west up the Colne valley to Colchester. The main part of District No. 1 is at Peldon, Langenhoe, and Strood Mill, but there are two well-marked outliers, one at Wivenhoe and another at Mortimer in Mersea Island. At and near Wivenhoe the intensity of the shock seems to have been greatest at low levels, and such a supposition would explain the character of that outlier, but no such explanation is applicable to the outlier at Mortimer, since the chief damage there is at a high level, and I was unable to discover any reason for its local character.

A great part of my attention was directed to such facts as indicated the direction in which the disturbance moved. The mate of the *Glimpse* was on deck, and says that the yacht was first, as it were, moved violently forwards to the west, and then even more violently backwards to the east. All the circumstances of the case make this a very good observation. In trying to determine the direction of the shock from the effects, I have taken great care to select such cases as would mark the first shock, and not the recoil. Unless this be done, no true result could be obtained, since very commonly the chimneys at one end of a house have been thrown down by the direct shock and those at the other end in the opposite direction by the recoil. On the whole I was able to observe nineteen cases which I looked upon as satisfactory. Almost all these vary from east to south. Perhaps the shock was rather more from the east at Wivenhoe than at Peldon. The mean of the whole is very nearly true south-east, which may be said to agree with the axis of chief disturbance as laid down by me on the map. The only case which is doubtful is that of the church at East Mersea. The manner in which two portions of the tower have been thrown down seem to indicate a shock from north-west. If this could be relied on with perfect confidence, it would show that the church lay on the south-east side of the vertical line, but I saw nothing else to confirm such a conclusion, and I think it quite as probable that the damage was done by the recoil which over the greater part of the district was from that same north-west direction. If this supposition is correct, the shock came up from below somewhat obliquely from south-east under East Mersea, where scarcely any damage has been done, and was most violent along the stroke of the wave at a distance of about three miles to the north-west. This and the general character of the area of chief disturbance seems to me to point to some very irregular distribution of hard rocks at a considerable distance below the surface. H. C. SORBY

Yacht *Glimpse*, Queenborough, May 25

IN your issue of the 8th inst. (p. 31) Dr. J. E. Taylor draws attention to the fact that sound preceded the Langenhoe earthquake for an appreciable period of time. A similar phenomenon has often been recorded, but as I cannot just now quote another instance, allow me to put forward a personal one.

On the morning of Monday, July 11, 1853, I had just gone to bed when I heard a heavy fast-approaching rumbling sound coming from the direction N.W. ¼ N. I was in St. Jean de Luz, and had stopped at an inn which skirts the high road from Bayonne to Madrid. The noise was coming nearer with the speed of an express train, and knowing that the only heavy coach which plied in those days could not pass at such an hour, I concluded that an earthquake was coming and got up to look at my watch, which I had left on a table at the opposite corner of the room; it was 20m. 8s. past midnight. When the noise seemed to issue from the ground *under* me, the whole house shook; it was then 24m. 8s. past midnight. Although occurring at a time

when most of the inhabitants were asleep, this earthquake was recorded in all neighbouring villages and at Vera, on the south of the Pyrenees chain. This contradicts the observations made in Japan, where mountains seem to stop earthquakes. Taken unawares at St. Jean de Luz, I did not note down how long the sound lasted before and after the shock. This should be attended to, if possible, in all similar phenomena, for we have as yet no permanent self-recorder of sound.

Although notable earthquakes are of rare occurrence in Europe, slight ones frequently happen. I have observed two microscopical ones near Hendaye. Our imperfect knowledge of their times and causes would be improved if our meteorological observatories had proper seismometers telling their own tales. Perhaps they should be of three kinds: for serious earthquakes, for slight shocks, and for earth-tremors.

ANTOINE D'ABBADIE, de l'Institut

Paris, May 26

THE earthquake was felt by an invalid in bed at Dudbridge, a mile south-west of Stroud, Gloucestershire. The house stands on the Middle Lias. It was also felt at Stonehouse, three miles west of Stroud on the Lower Lias. The New Red dips under the Lias, about seven miles west of Stonehouse, at the well-known section at Westbury-on-Severn. It is presumed that the Carboniferous Limestone exists under the New Red. It is visible three miles to the west of Westbury.

A. SHAW PAGE

Instinct in Birds

I READ with special interest the letter signed "Wm. Brown" in NATURE of the 15th (p. 56). I regret I cannot see the letter to which it refers. My excuse for intruding on your limited space is that I have something to say about a magpie's nest. My text is words in Mr. Brown's letter, "I have often seen the nest shot down." Some years ago seeing a magpie fly from her nest I climbed the tree to see what was in it. I found six eggs, but *not magpies'*. They were *starlings'* eggs on which the magpie was sitting. I visited the tree several times, and always found the magpie sitting on the starlings' eggs. To my great regret, on finally coming to see how the magpie and her foster brood were getting on, I found a shot-hole through the nest, and magpie and eggs knocked to pieces.

R. S. S.

Edinburgh, May 21

P.S.—My regret was the greater as I could easily have prevented this by asking a neighbour's keeper to let the nest alone. The magpie lays as a rule seven eggs. There were six starlings' eggs in the nest. I saw no starling near the place, and as it was in the middle of a dense fir wood, I was the more astonished to see starlings' eggs there.

A Remarkably Brilliant Meteor

TO-NIGHT, about 10.45 p.m., I was "stepping westward," about half a mile east of my house. Suddenly the ground before me was lighted up with noontide splendour by a luminary that was above me and behind me. Looking back I saw a meteor a good deal east of the Great Bear, and nearly as high in the sky. It was about as big as Venus, and of the same hue. It was speeding from north to south with a slight descent. Its course very soon came to an end. It left behind it a streak of duller lustre: this phosphorus-like trail vanished almost at once. The career of this meteor while that body was visible here, lasted little, if at all, longer than a minute, but its light was remarkably brilliant.

MODERN TRAVEL—A SCIENTIFIC EDUCATION

THE teaching of geography has come to rather a sad pass in this country, as was evident from the address of the President at the Anniversary of the Royal Geographical Society on Monday. The Society's examiner, Prof. Moseley, reports that it is entirely neglected in our public schools; and the Council of the Society have withdrawn the public schools medals which they have awarded for years, simply because there are so few candidates for them. In our great public schools geographical teaching has no recognised place; if taught at all it is only as a voluntary subject, which may or may not be taken at the caprice of the boys. Some attempt has been made to methodise the teaching of the subject in schools under Government inspection, but so far the result has not been very successful. No doubt the Science and Art Department and the University examiners have done much to improve the teaching of what is known as physical geography in our middle-class schools; but at the very best we are a long way from perfection in this important branch of education, which, were it not for unintelligent teachers and dry text-books, ought to abound with interest. One serious defect in our system of teaching the subject is the want of proper apparatus; maps are good enough in their way, but it is not easy to persuade the pupil that they represent anything more than a flat surface. They are a poor substitute for the models which we find in some Continental schools, supplemented as these are by large-scale, well-executed pictures of the leading natural and artificial features with which geography deals. If Miss North's gallery of pictures at Kew could be taken round the country at intervals for exhibition to our schools, it would do more for giving a real conception of what geography is than many text-books. Let us hope that the step taken by the Royal Geographical Society, in appointing an inspector to visit Continental schools and report on the whole subject, will lead to real reform.

Of course the most effective and impressive method of education in geography would be to take the pupil all over the world, and let him see with his own eyes the many wonderful and beautiful features of our earth, which as lists of dry names weary his soul in his text-book. This is a method recently followed to some extent in certain of the French high schools. The best pupils are taken during the vacation to some important foreign centre, like London or Berlin, Christiania or Stockholm, from which excursions are made to the leading natural and artificial features of the country. Every tourist is indeed more or less of a practical geographer, finding fresh energy, education, and interest in those very things which when at school he abhorred. But we fear that many tourists pass through a country, if not with their eyes closed, at least without any training whatever as to what they are to look for; and unless the best-intentioned tourists have been so far instructed, their travels will do them little good. Hence the great educational value of a carefully-compiled guide-book; and how important such a guide-book might be made as a means of geographical and scientific instruction may be seen from the handsome "Orient Line Guide" before us.[1] It is in most respects very different from any of the volumes with which Murray and Baedeker have made us familiar. It is meant neither for knapsack nor pocket, but evidently for the saloon table. It is a broad folio, handsomely printed and abounding in fine large-scale illustrations and maps by Maclure and Macdonald. Every one who has gone a long voyage must have felt its tedium in spite of amusements of all kinds; but with the aid of the "Orient Guide" every day ought to bring fresh interest and fresh means of instruc-

[1] "Illustrated Guide of the Orient Line of Steamships between England and Australia." Issued by the Managers of the Line. (London: Maclure and Macdonald.)

tion. The illustrations themselves are of much interest; plans and portraits of several of the magnificent ships of the Line, views of many places and scenes from Gravesend to New Zealand, star-charts which may furnish a nightly education in astronomy as well as navigation, and maps of all the countries along the route.

When we say the work is edited by the Rev. W. J. Loftie, it will be evident that it is of an unusually high stamp. The special feature of the text is that besides the information about the Line and its ships, instructions to passengers and such like useful hints, we have special articles on seamanship, navigation, natural history at sea, and weather at sea. All the leading features along both the Suez route and the Cape route are pointed out and information given about them as the voyage proceeds, while special chapters are devoted to all the Australian colonies, to Egypt, the Holy Land, Italy, European cities, and the mother country. Thus it will be seen that the "Orient Guide" is adapted for the use of voyagers from both ends of the route.

As a means of conveying some practical knowledge of science, and arousing an interest in the subject, the chapters on seamanship, navigation, meteorology, and natural history must be particularly useful. Under "Seamanship" we are informed about all the most important points in the structure and working of a vessel. Such common terms as "running," "reaching," "beating," are explained, as are also the causes of the various motions of a ship—rolling, pitching, scudding, and so on; the various rigs of ships, the different species of ropes and knots, the various phrases shouted in working the helm, and other terms in nautical phraseology. The chapter on navigation ought to be particularly welcome to landsmen; by means of it the mere progress of the vessel itself, the daily operations of the officers in connection therewith, the conduct of the compass, the reading of charts, the use of the sextant, the various methods of ascertaining longitude, the use of the log, and so on—all can be made to furnish the passenger with constant sources of interest, and give him some idea of the many and complicated scientific principles which underlie so apparently simple a matter as the navigation of a steam vessel. The chapter also contains much information about the stars and their utility to navigation. The star-charts which accompany the chapter are not overloaded with names, and will be found of real utility in detecting the leading stars and watching their nightly changes as the vessel proceeds on her course.

The chapter on natural history contains succinct information on the leading forms of animal life likely to be met with during the voyage—land, coast, and ocean birds, fish of various kinds, cetaceans, the nautilus, zoophytes; while the marvellous phenomenon of the luminosity of the sea is explained. By a study of the chapter on the weather at sea, passengers may be able to throw more intelligence and variety into that monotonous and never-ending topic of conversation.

The more purely geographical part of the work is done in considerable detail. All the features met with on both routes are described in the order of their occurrence. Then for the benefit of those going out there are several chapters on the various Australian colonies, on their various aspects, scientific, geographical, and economical. On the other hand, for the benefit of Australians there is a general chapter on European travel, and special chapters on Egypt, Sinai, and the Holy Land, Italy, European cities, and the mother country—all richly illustrated.

Thus it will be seen that the "Orient Guide" is something very different from the ordinary run of guide-books, and that with it as a constant companion on board ship, a voyage to or from Australia may be made a real education. We should like to see other companies follow the example so well set by that of the Orient Line; travelling by sea has now become so common that thus the serious defects of English education in geography might be largely remedied. But even the railway companies might follow the example. Several years ago we noticed a geological guide to some of the United States railways, in which the various formations along the routes were described in the order of their occurrence as the train proceeded. Something of a similar kind might very well be done for English railways, extending the programme, however, to other features besides those relating to geology. Meantime the Orient Line is to be congratulated on its enterprise, and on the intelligence which has guided the compilation of their handsome work. Mr. Loftie has not only edited the work, but written the chapter on Egypt, while other special subjects have been treated by Dr. Charles Creighton, Mr. G. Baden Powell, Commander Hull, and Mr. H. E. Watts.

THE LATE MONSIEUR WURTZ

We have received the following communication from a Paris correspondent:—

The *éloges* pronounced over M. Wurtz's grave and your estimate of his place in science, doubtless being prepared, will tell your readers the extent of his life-work as a chemist. Indeed the best monument that could be raised to his memory would be a list of the work that has come from the laboratory at the École de Médecine during his thirty-four years' direction. But your readers may perhaps also be interested to know something of M. Wurtz as he appeared to those who were his pupils at the time of his death.

The impression one had at the beginning of M. Wurtz's first lecture was one of utter surprise. Organic chemistry was no longer a dry science full of dry formulæ, tiresome, complicated and difficult to remember; for the whole series of chemical transformations appeared as some philosophical romance in which the atoms and groups of atoms had their own particular characters, and could in given circumstances be depended on to act in a particular way. Yet, notwithstanding the picturesqueness of expression, there was no sacrifice of scientific accuracy. His teaching was so skilfully designed that each of his phrases could be interpreted immediately by the theories of thermo-chemistry and dissociation, which the more advanced student would learn later to apply to the study of organic chemistry, and by whose help the science is being gradually brought more and more to a purely physical stage. In the same way the psychology of the individual characters in life may some day be capable of being interpreted by purely physiological results. But notwithstanding the assertions of some eminent chemists, and notably of Wurtz's great rival Berthelot, no more in chemistry than in psychology is the problem thus reduced to one of rational mechanics. It seems, on the contrary, that for the accomplishment of this end account must inevitably be taken of those atoms for which Wurtz fought so hard, and of which Berthelot and the École Normale still deny the probable existence.

Taken aback at first by the new way of presenting well-known facts, one was soon carried along by the stream of Wurtz's eloquence and by his enthusiasm; and as one came out of the theatre, though Wurtz never left his subject to go into transcendental digressions, one had a feeling of being raised from the common things of life—a feeling of being better in every way for the new revelation of scientific truth.

Wurtz's eloquence was exceeded only by his modesty. He spoke of and praised Hofmann's general method for the preparation of the compound ammonias without mentioning the fact that it was he who discovered and recognised the first compound of this type. He eulogised Berthelot's great discovery that glycerine is a triatomic

alcohol, then spoke of the diatomic alcohols or glycols; but no one in the audience could have guessed that it was he who first gave an accurate interpretation to Berthelot's results, and that he followed up and confirmed his generalisation by the brilliant discovery of the glycols.

I cite but two cases out of many, for during the whole of his course Wurtz never alluded to one of his discoveries as being his own; and certainly from his own lectures his large audiences at the Sorbonne could have had no idea of the leading part he played in the grand development of modern organic chemistry.

Having already exercised his immense influence at the École de Médecine, he felt himself at too great a distance from his auditors at the Sorbonne, and while he was having a laboratory (still unfinished) built for him, he inaugurated last year a series of weekly *conférences*[1] under his own direction, which might well find their analogues in the English Universities. Each week M. Wurtz gave out two subjects (such as molecular weights, the paraffins, the ethers, &c.), and two students volunteered to give lectures (lasting from half an hour to three-quarters of an hour) on them the week following. The *conférences* were delivered in one of the large lecture-rooms to audiences of from sixty to eighty students; Wurtz himself sat at the end of the lecture-table and gave a kindly and helpful criticism after the *conférence* was over. The last of these *conférences* was given just three weeks ago by the writer of these lines, and M. Wurtz's kind words will always be a precious memory to him:—they were the last he was destined to utter in public.

Wurtz was a fine man, of commanding presence. To alleviate the organic disease from which he suffered, and from which he died, he began by his doctor's orders to work at gymnastics about ten years ago, and he was, notwithstanding his sixty-six years, an accomplished gymnast at the time of his death. The untiring activity of his mind appeared in a certain vivacity and restlessness of manner peculiar to himself; but one felt, as soon as one saw and spoke to him, that he was a straightforward, loyal-hearted gentleman.

M. Wurtz was followed to the grave not only by the official deputations from the Sénat, the Institut, and the various learned institutions with which he was connected, but also by hundreds of students, principally from the École de Médecine and the Faculté des Sciences, bearing, according to French custom, wreaths of flowers, and thus paid their last tribute to the memory of their loved master. One could not help noticing especially an immense wreath of white flowers, offered by the women-students of the Faculté de Médecine, as a testimony of their gratitude to the man who some fifteen years ago obtained permission for them to study in the Faculty, and whom they followed to his last resting place right across Paris from the Boulevard St. Germain to the cemetery of Père la Chaise.

The sympathy which M. Wurtz inspired in all with whom he came in contact, coupled with his great genius, gave him a personal influence beyond that of most men—for if he is dead to us in the body he is still living in the mind, aye, and in the hearts, of the thousands of students who have listened to him in rapt attention on the benches of the École de Médicine and of the Sorbonne. As he said of Dumas: *Forma mentis æterna.*

Paris, May 16

ROBERT ANGUS SMITH

ANOTHER of the men of the middle time has passed away. Early on Monday morning, the 12th inst., whilst Adolphe Wurtz lay dying at Paris, Angus Smith breathed his last at Glynwood, Colwyn Bay. Both men were of the same age, and both were pupils of the illustrious Liebig—students in the great chemical school of Giessen. Each, in a sense, was imbued with some one phase of the spirit of their many-sided master, but in a different manner: Wurtz spent his energies and won his greatest triumphs in the development of chemical theory, and in the elucidation of the structure of organic compounds; Smith had probably little knowledge of, and but little sympathy with, the theories of modern organic chemistry; and although possessed of his countrymen's love of metaphysics, and, as his writings show, capable of much abstract speculation, his conceptions of chemical constitution were probably, in the main, as mechanical as those of Dalton, whose disciple and chief interpreter he considered himself to be. His chief point of contact with Liebig lay in his recognition of the utilitarian side of his science: for upwards of forty years he laboured unceasingly to show how chemistry might minister to the material comfort and physical well-being of men—not in the manufacture of new compounds useful in the arts, or in the establishment of new industries,—but in raising the general standard of the health of communities by checking or counteracting the evils which have followed in the train of that enormous development of the manufacturing arts which is the boast of this century. Sweetness and light were fixed articles in Smith's creed. His love of fresh air, of pure water, of a green hillside was intense. "Where to, sir?" asked a cabdriver whom Smith had hailed on his way home, tired and longing for escape from beneath the dull, murky Manchester sky. "To the sun!" was the answer. And we are told that it was to the credit of that cabman that he did not take the old philosopher to some hostelry with the sign of Phœbus, but trundled him among the green lanes beyond the city's outskirts until it was time to turn the horse's head homewards. To keep the air in our towns fresh and wholesome, to restore the water of our streams to its pristine clearness, to preserve the freshness and verdure of the fields and woods, to sweeten the atmosphere of the crowded dwellings in cities,—this was the kind of work to which Smith dedicated his life, and at which he laboured to the very last. There have been greater chemists, no doubt; his name is not associated with any fundamental discovery in chemistry, and his attempts at theorising were not always very happy; but in his true vocation, as the chemist of sanitary science, Smith worked alone, and we have yet to find the man on whom his mantle has fallen.

Robert Angus Smith was born in the neighbourhood of Glasgow on February 15, 1817. When nine years of age, he was sent to the High School, and at thirteen he entered the University of Glasgow. He quickly showed that liking for the classics, and especially for Greek, which clung to him through life, and his mother, as usual among Scottish matrons, cherished the aspiration that her son should "wag his pow in a poopit." Whether this ambition was ever shared by her son is doubtful; at all events, such a career became impossible for Smith after hearing the preaching of Campbell of Row: he declared that he could not take "holy orders in a kirk which had expelled a man for being apparently both wiser and better than itself." On leaving the University he acted as tutor in various families in the Highlands and in London. What directed him towards science does not appear. In company with his brother John, who is known as the inventor of a chromoscope, and as the author of some speculations on the cause of colour and the nature of light, he had read the standard works of his time on natural philosophy and chemistry. When twenty-two years of age he found himself at Giessen, and after working under Liebig for some time he obtained his doctorate. He returned to England in 1841, and procured employment under Dr., now Sir Lyon, Playfair, in connection with the Health of Towns Commission. It was this circumstance which doubtless served to fix the direction of his future work. His earliest publication—a contribution to the then recently founded Chemical Society of London—was a paper on the air and

[1] I need hardly say all University lectures are quite free in France.

water of towns, and successive memoirs, with almost identical titles, made their appearance either in the Society's *Transactions* or among the Reports of the British Association. The Royal Society's Catalogue shows that Smith was the author of about thirty papers on air and water. These he eventually collected and published, with considerable additions, in the form of a thick octavo volume, entitled "Air and Rain, the Beginnings of a Chemical Climatology," with a dedication to his friend and teacher Liebig. This book shows Smith at his best and at his worst. It is full of facts and quaint out-of-the-way references; on the other hand, it is diffuse, and, as a piece of literary work, badly put together—faults difficult to avoid in a compilation based upon, or largely composed of, papers already published. That Smith had considerable literary skill, and a sound critical faculty, may be seen in the short memoir on Graham prefixed to the collection of that philosopher's papers brought together and published, with a reverential care, by the late Dr. James Young of Kelly. Smith had years before saturated his mind with the notions of the Hellenic atomists, even before the time he wrote his monograph on Dalton, and in this short prefatory memoir of some twenty pages he crystallises out his thoughts on the development of the atomic systems of Kapila, Leucippus, Lucretius, Newton, and Dalton, and shows with admirable lucidity Graham's true relation to these great thinkers. Smith, however, would never have made a good teacher, despite his wish, in early life, to connect himself with some place of higher chemical instruction. When at his best he was not an ineffective speaker; but he was wanting in power of exposition, and his metaphysical tendencies and his quaint playful fancy were only too apt to disturb the even tenor of a sustained description, or closely reasoned argument. No man, however, was more popular among young men, for he had a genuine sympathy with youthful aspirations, and a kindly way of drawing out and encouraging what was good in them, and there are dozens of men still living who have to thank the gentle, quiet-spoken philosopher and friend for their first step in life. He had, too, his countrymen's tenacity of friendship: it took a very violent wrench indeed to disturb a confidence once placed.

From 1842 Smith was closely connected with Manchester. In that year he settled himself in the town as a consulting chemist. Shortly afterwards he became a member of the Literary and Philosophical Society of Manchester—a society made famous by its connection with Dalton and the Henrys—and much of his work appears in the *Memoirs* and *Proceedings* of that body. In 1855-56 he became one of its honorary secretaries, in 1859 a vice-president, and in 1864-65 president. In his "Centenary of Science in Manchester," published a short time ago, he has sketched, in characteristic manner, the growth of that institution, and has sought to trace its influence on the development of scientific life in Lancashire.

In 1863 Smith was appointed Inspector-General of Alkali Works for the Government, and the somewhat delicate task of initiating the working of Lord Derby's Act fell to him. He performed this duty with characteristic tact and with every desire to avoid undue interference with the legitimate business of the alkali maker. The successful working of that Act is largely due to the manner in which Smith and his subordinates set it in operation. On the passing of the Rivers' Pollution Act he was made Inspector for England, and afterwards for Scotland. He held both these appointments up to the time of his death.

Angus Smith had a passionate delight in the Highlands, and the smell of a peat fire was to him as incense. He had something, too, of the Highlander's love of mysticism in his composition, and throughout his life he found pleasure in Celtic literature; and it was with a mind well stored with legends that he produced "Loch Etive and the Sons of Uisnach," published anonymously in 1879.

Smith lived the "quiet life" of Pope's philosopher. His temper was singularly even and placid: he had his checks and crosses, of course, like other men, and he was occasionally pained to find himself misunderstood. But nothing ruffled his calm. His perfect transparency, his charming simplicity, and a certain quiet playfulness of manner gained for him the sobriquet of "Agnus" Smith. Indeed, his sense of fun could see the latent humour in any situation. Even on his death-bed it was with him. Somebody had said that they were not going to part with him yet. "You will be clever people," he rejoined, with the old twinkle in his eye, "if you keep me here three days longer."

Smith became a member of the Chemical Society in 1845, and a Fellow of the Royal Society in 1857, and in 1882 the University of Edinburgh conferred the honorary degree of LL.D. upon him.

T. E. THORPE

NORWEGIAN GEODETICAL OPERATIONS[1]

THE first part of this publication, published in 1882, was reviewed in NATURE, February 8, 1883. The second part, now before us, consists principally of a series of tables giving the results of the observations at the following tidal stations:—Stavanger from 1881 to 1882, Throndhjem from 1880 to 1881, Kabelvaag from 1881 to 1882, and Vardoe from 1880 to 1882. These tables are arranged precisely as in the first part; it is therefore unnecessary to refer to them more particularly.

A description, accompanied by a drawing, is given of the self-registering apparatus used. The float, placed in a tube, is connected by means of a fine wire to a wheel 50 cm. diameter, and the wire is kept taut by a counterweight acting on a second concentric wheel. On the axis of these wheels, and rigidly connected to it, is a pinion 2·5 cm. effective diameter, working on a horizontal rack, to which the scribing pencil is attached. Thus the rise and fall of the tide is measured to a scale of $\frac{2 \cdot 5}{50}$ or $\frac{1}{20}$. A cylinder, on which is fixed the diagram paper ruled with hour lines, is placed horizontally below the rack, and is driven by a clock connected to it directly by means of gearing, and assisted by a weight attached to a string passing over a pulley. This apparatus is the invention of Lieut.-Col. Haffner, and is made by a watchmaker (G. P. Stenberg) at Bergen.

It is mentioned that, owing to a defect in the self-registering apparatus used at Oscarsborg and at Drontheim, and described in the first part, the observations are not as satisfactory as might be wished. In the instruments used at these stations the motion of the driving clock was communicated to the diagrams by means of a string, and it has been found that the variations in the amount of humidity and of temperature sufficiently affected the length of the string to cause appreciable errors. It should be understood that the readings were taken by means of hour lines ruled on the diagram paper; any alteration in the length of the string clearly affects the accuracy of the position of these hour lines. This source of error has been removed, and new observations taken, which will be published in a succeeding part.

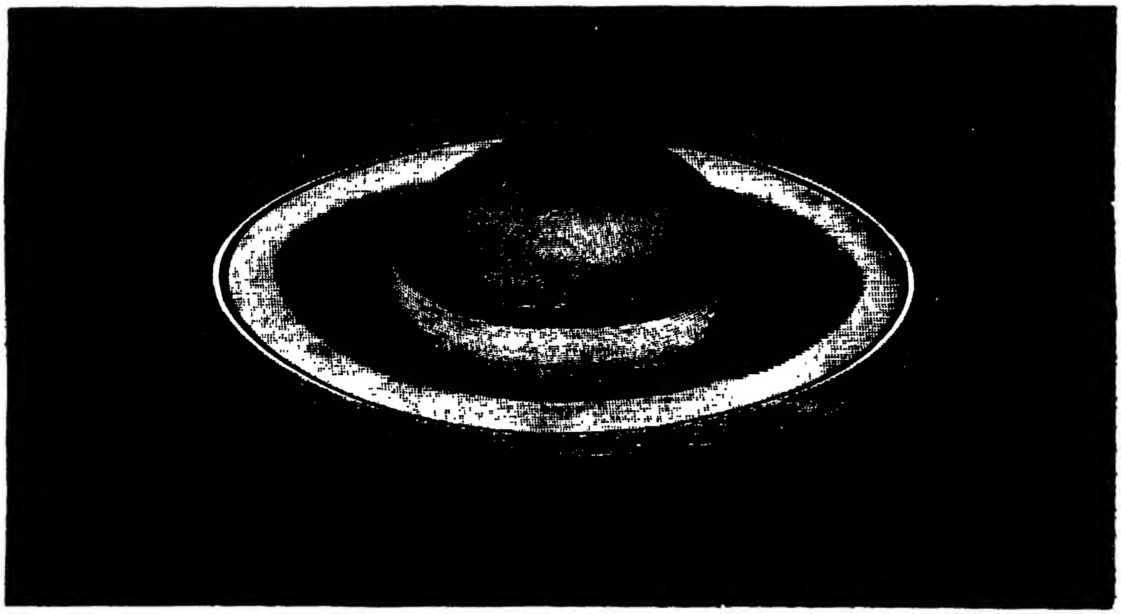
SATURN

MESSRS. PAUL AND PROSPER HENRY contribute to *La Nature* some interesting information on the recent aspect of the planet Saturn. During the month of February and the beginning of March last

[1] Publication of the Norwegian Committee of the Association for the Measurement of Degrees in Europe, Part II. (Christiania, 1883.)

several nights were of exceptional purity so far as regards the definition of stars observed in the telescope. Messrs. Henry say:—

"We took advantage of the most favourable moments to observe with our refractor of 0·38 m. the aspect of the principal planets; Saturn and his rings attracted our especial attention. The representations of this planet were often of remarkable precision, even when magnified more than a thousand times. It was possible to notice on several occasions curious inequalities in the equatorial band. Outside the known rings we established, around the principal separation (Cassini's division), the existence of a new ring, brilliant and perfectly defined, having a breadth of about 1½″. It is surprising that this ring, which is quite visible, has not hitherto been perceived. But the fact which more particularly struck us in observing Saturn, and which has induced us to publish the accompanying sketch, is that, notwithstanding extremely favourable conditions of visibility, it was impossible to discover the least trace of the external *anse* (Encke's division). That division, indicated since Encke by all the observers who have published drawings of Saturn, and which we believe we had also seen with instruments of moderate power, may well be only the result of an



Aspect of Saturn, March 4, 1884.

optical illusion. This phenomenon would be produced, in our opinion, by the brilliant ring which we have discovered, and which irradiation causes to appear larger than it really is, while by an effect of contrast we believed we saw, like a black line of separation, what in reality is only a marked difference in the brightness of the rings. By examining at a distance of about three metres the sketch here given, this division may be very clearly noticed as it is usually represented. The experiment will succed even better if one takes the precaution of slightly closing the eyelids. In these conditions the aspect of the drawing is pretty much that which Saturn presents when observed with instruments of ordinary dimensions, or even with powerful telescopes when the definition is imperfect. We may then explain by an optical illusion these differences of aspect observed in the external ring, without its being necessary to attribute them to any modification which has taken place in this curious appendage of Saturn. This interesting planet is now too near the sun for useful observations to be practicable. We shall continue our researches by means of powerful telescopes at the next opposition."

EARTH CURRENTS[1]

ONE of the most interesting subjects dealt with at the recent Electrical Congress in Paris was earth currents. The absence of published information in France on the behaviour of these erratic disturbers of telegraphic peace has led to an elaborate and careful study of the whole question by M. Blavier, the well-known and distinguished director of the High School of Telegraphy of the Post and Telegraph Administration in France. This has been printed, published, and circulated by the Minister of Posts and Telegraphs (M. Cochery) for the use of the members of the recent Congress.

These earth currents are always present in telegraph lines, varying in geographical and electrical direction and in strength, generally scarcely perceptible, but sometimes acquiring such intensity as to acquire the title of "storms." Their direction depends upon the direction of their earth terminals, and in no way on the route of the wires or on the fact of their being overground or underground. The longer the line the greater their strength. Their strength and direction vary with the hours of the day, and they show well-marked periods of maxima and minima. In fact there appears to be a tide in their affairs clearly following solar influence, and it has been believed by more than one observer that the influence of the moon is also perceptible. There is also an annual period of maximum and minimum, and this follows the well-marked eleven-year period of sunspots. We have just been passing through a period of maximum intensity. 1881 and 1882 were years of considerable activity. Their vagaries are exactly coincident

[1] 'Étude des Courants Telluriques," par E. E. Blavier. (Paris: Gauthier-Villars, 1884.)

with the variations of the mariner's compass, and are evidently primarily due to the same cause. It is when the aurora is present that they acquire extraordinary energy, and change their direction and intensity with great rapidity. Their effects are then observable simultaneously over the whole globe. They interfere seriously with the transmission of telegraph messages.

They have been studied and examined with great care in England. The eminent engineer, Mr. W. H. Barlow, F.R.S., was the first in the field, and his paper before the Royal Society in 1846 has scarcely been improved upon or added to. The late C. V. Walker was an incessant observer, and sent several papers to the Royal Society. Varley added considerably to our knowledge, and there are several papers by Mr. Preece, F.R.S., on their behaviour. The latter remarked that in the great storm of January 31, 1881, the currents acquired an electromotive force of ·3 volt per kilometre of earth surface and an intensity of 30 milliamperes—currents far stronger than those used for telegraphy. The *Proceedings of the Society of Telegraph Engineers* contain several interesting communications from Adams, Dresing, O. Walker, W. Ellis, Saunders, and others. It was warmly discussed at the Congress of 1881, which decided (1) that certain short lines in each country, independent of its general telegraph system, should be exclusively devoted to their study; (2) that long lines, particularly those underground, should be utilised as frequently as possible for the same purpose,—lines N. and S. and E. and W. being taken by preference, and one day per week—Sunday—being simultaneously employed for the purpose.

It was also suggested that during the year 1883 the 1st and 15th of each month should be taken for separate and careful observation. These resolutions have been faithfully carried out in Paris, and M. Blavier's work is the consequence. They have also been followed with great advantage in Germany and in Russia.

Permanent wires at right angles to each other have for many years been fixed and used in Greenwich, but the observations have not been systematically published, though the records are photographically printed.

M. Blavier has, since September 1883, organised a very careful system of automatic observation, by employing a clockwork apparatus similar to that designed by M. Mascart to register simultaneously the three components of terrestrial magnetism. He uses the dead-beat galvanometer of Deprez and d'Arsonval, shunted so as to meet the cases of all currents. As the chief point to be determined is the difference of potentials at the ends of a circuit, M. Blavier made the resistance of each long circuit examined equal to 10,000ω, and each short circuit 1000ω. The ordinates of the curve traced give indirectly the electromotive forces present. His excellent memoir contains a series of these curves, and very instructive they are. A complete lunar month from February 28 to March 28 is given. Observations were taken on aërial and underground wires. The general direction of maximum electromotive force in France is N.W.—S.E., making an angle of 56° with the magnetic meridian. M. Blavier concludes from the deflections of the needles that the disturbances of the magnetic elements are due to accidental electric currents circulating in the higher regions of the atmosphere although the earth currents circulate in the crust of the globe. He favours De la Rive's theory of the aurora borealis as being due to the circulation of electric currents in the higher regions of the atmosphere, in support of which he mentions several atmospheric effects well recorded as simultaneous with earth currents, such as intense scintillation of the stars observed by Montigny, and tempests. He associates earth currents with trade winds, and thereby indirectly with the sun.

Altogether M. Blavier's *brochure* is very ably written and a credit to the department of which he is such an old and distinguished member.

NOTES

THE French Minister of Education and the Fine Arts has proposed to place at the disposal of M. Pasteur, for the prosecution of his scientific experiments, a large domain situated at Villeneuve-Etang, which belongs to the State.

COLONEL DONNELLY has been appointed Secretary and permanent head of the Science and Art Department of the Privy Council.

THE Paris Academy of Sciences has nominated M. Cailletet, the inventor of the apparatus for the liquefaction of gas, a *Membre libre* in place of the late M. du Moncel. The Academy has appointed a Commission of six members to prepare a list of candidates for the office of Perpetual Secretary.

THE death is announced of M. Bontemps, the author of several volumes on pneumatic telegraphy, and engineer to the French Government for the construction of the Paris system.

A COMMITTEE has been formed at Alais (Gard) for erecting a statue in that city to M. Dumas. A committee will also be established for the erection of a statue to M. Wurtz in Paris.

THE election of Dr. C. S. Roy to the new Professorship of Pathology at Cambridge augurs well for the scientific development of the rapidly-increasing medical school of that University. Dr. Roy's work, both as George Henry Lewes Scholar and as Professor-Superintendent of the Brown Institution, has, it is well known, been of the highest merit and promise.

THE *conversazione* of the Institution of Civil Engineers takes place to-night at the South Kensington Museum.

WE are pleased to learn from a correspondent that the Natural History Department of the University of Edinburgh has undergone remarkable development during the last six months. Two years ago it had no lecture-room, and only one small room serving both as museum and laboratory. Now the old chemistry class-room, in which graduations and other ceremonials used to be held, and which is still the largest class-room in the University, has been handed over to the Professor of Natural History. There has not been time to have the class-room reseated, but the comfort of lecturer and students has been cared for in a still more important way, viz. by the erection of a ventilating fan, which changes the air several times every hour. The great demand for practical teaching which marked Prof. Ewart's advent to Edinburgh could only then be met with by resorting to a remote corner of the College buildings. Now the practical work is carried on in a splendid, beautifully decorated, well-lighted hall—a dingy museum in Jameson's time, but now capable of accommodating about 130 men at a time. In addition to this laboratory there is an adjacent smaller work-room for advanced students. A series of tanks is in process of erection in the lower room, which corresponds in size to the large laboratory, and which it is intended to convert into a laboratory provided with all the necessary apparatus for studying the life-history and development of marine organisms. When the other rooms which formerly belonged to the Natural History Department are added, the arrangements for teaching zoology in Edinburgh will be alike complete and satisfactory.

WE understand that the University of St. Andrew is about to approach the Government with the view of obtaining funds for extending the Natural History Museum and at the same time for providing a marine laboratory within the walls of the University, while the more practical work of hatching, &c., which the Fishery Board for Scotland is carrying on will be provided for

by a laboratory on the cliff immediately behind the College. It is proposed to prosecute the more purely scientific work within the walls of the College itself. The College is so near the proposed hatchery that the same pumping apparatus will serve for both laboratories, and thus, when established, the working expenses will be comparatively trifling. If the University and the Fishery Board succeed in carrying out their plans, biology will receive a mighty impulse at St. Andrew's, and the famous bay once more be peopled with an abundant supply of fish.

THE Clothworkers' Company have voted 2000*l*. towards the fund of 20,000*l*. required for the complete equipment of the new Central Institution of the City and Guilds of London Institute, this being additional to their original building grant of 10,000*l*. and their annual subscription of 3000*l*.

WE learn that orders have been given by the Inspector-General of the Imperial Maritime Customs of China, that meteorological observations made in the Treaty Ports and in the lighthouses are in future to be sent to the Government Astronomer at the Hong Kong Observatory, but that it is not at present the intention of the Chinese Government to start a meteorological service in China. With regard to observatories great progress has been made of late years. Central Government observatories exist in Japan, Peking (Russian), Hong Kong (British), and Batavia (Dutch), while the different Australian colonies which are covered with a network of minor meteorological stations, possess numerous central observatories, and it is very likely that this row of observatories will be extended further south, as steps are being taken to found an observatory in New Zealand, while the Russian Government is likely to extend its stations to the north of Vladivostock. First-class observatories are also supported by the Jesuit Order in Corea, China, and Manila, as well as elsewhere. For the investigation of typhoons, the terrible scourges of the China Sea, Father Faura, at Manila, has done most important work, and the utility of his observatory cannot but be extended when the Chinese Customs start self-recording meteorological instruments at South Cape, Formosa. But while each observatory is individually engaged in studying the peculiar features of its local climate in all its vicissitudes, it is by a comparison of the results exhibited in the different annual volumes published by each of them that we gain an insight into the laws that govern the general motions of the atmosphere and which underlie the peculiar features of each local climate. Thus in the China Sea the typhoons originate from local causes (heat and moisture), but the form and direction of their tracks are determined by the general laws of atmospheric motion in these regions.

THE first Circular of Information issued this year by the United States Bureau of Education relates to the approaching International Prison Congress at Rome in October next. The Bureau considers that the work of education is by no means limited to good children; and certainly, if no other power takes the reformation of the vicious in hand, their reform does become by so much the most important part of the work overlooked by this office, as they that are sick more need the physician than they that are whole. Prison Congresses were held in Europe in 1845, 1846, and 1857, and after an interval were revived through a paper by Count Sollohub of Russia, published in the Report of the New York Prison Association in 1868. His suggestions were adopted by Dr. E. C. Wines, the Secretary of that Society, and a Prison Congress was brought together at Cincinnati in 1870. Dr. Wines was elected Commissioner to act at an International Congress, and he brought about such meetings, first in London, then in Stockholm, and now at Rome. The questions for consideration are:—(1) As to the advantages from a reformatory view of imprisonment, and whether more useful and less degrading labour, without forcible detention, or even simple admonitions, might not be less mischievous and more effectual; as to length of sentence; as to finding the instigators to crime; and the treatment of juveniles. (2) Upon prison architecture, the keeping of new away from old offenders, Prison Commissions, prison hygiene, dietary and education, the rivalry between prison and free labour, and the remuneration of the former, and the use to be made of Sundays and holidays in the interest of education. (3) International arrangements, repression of vagrancy, and the desirability of societies for the help of discharged convicts.

ANOTHER of the Bureau's publications is a Report of the School of Classical Studies at Athens; and although this hardly falls under the head of Nature studies, yet a journal of science may note with satisfaction the spread of a scientific spirit which feels how far clearer is the knowledge of history after imbibing such object lessons as must be gained from an acquaintance with the climate and aspect of the country, and their natural influence upon the race inhabiting it, from the scene of the philippic, the fight, or the festival.

"To expedite school business and diminish future controversies" the United States Bureau of Education has published a digest of 700 law decisions, which have been made since Col. Eaton has been in office, upon all the details of education in that country. The number of States, each independent of all the rest, has added greatly to the labour of such a digest, and its recommendation that, while variety of systems should be encouraged in different States, uniformity of system should be enforced in each State seems to combine the greatest amount of practical advantage.

THE following alterations have been made in the arrangements for the Friday evening meetings at the Royal Institution:—Mr. Willoughby Smith will give the discourse on June 6, on Experiments in connection with Volta-Electric and Magneto-Electric Induction; and on June 13 (extra evening), Prof. Dewar will give a discourse on Researches on Liquefied Gases.

MESSRS. CHAS. GRIFFIN AND CO. announce the publication of a "Year-Book of the Scientific and Learned Societies of Great Britain and Ireland." It will give some account of the constitution and working of more than 600 societies, distributed under the following heads:—(1) Science generally; (2) Mathematics and Physics; (3) Chemistry and Photography; (4) Geology and Mineralogy; (5) Biology, including Microscopy and Anthropology; (6) Economic Science and Statistics; (7) Mechanical Science and Architecture; (8) Naval and Military Science; (9) Agriculture and Horticulture; (10) Law; (11) Medicine; (12) Literature; (13) Psychology; (14) Archæology. There will also be an appendix giving a list of the chief scientific societies throughout the world.

MESSRS. W. SWAN SONNENSCHEIN AND CO. request us to announce that the whole edition of Profs. Nägeli and Schwendener's work on the Microscope, which has been in the press for so long a time, and which would have been ready for publication in a few days, was destroyed in the recent disastrous fire in Paternoster Row. A new edition has been at once sent to press, and it is hoped that the work will be in the hands of the public very shortly, since the English editors of the book had already completed their revision of the proof-sheets.

PROF. A. E. VERRILL, *Science* states, has in the press a very important paper, entitled "Second Catalogue of Mollusca recently added to the Fauna of the New England Coast and adjacent parts of the Atlantic, consisting mainly of Deep-Sea Species, with Notes on others previously reported." These are chiefly derived from the dredgings of the Fish Commission, are well illustrated, and worked up in the full and careful manner characteristic of the author. It appears in the *Transactions of the Connecticut Academy of Sciences*, and is illustrated by Emerton.

The additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus* ♂) from India, presented by Mr. J. L. Ellis; a Black-backed Jackal (*Canis mesomelas*) from South Africa, presented by Mr. H. P. Plummer; a Spotted Eagle Owl (*Bubo maculosus*) from Africa, presented by Capt. Larner; a Nicobar Pigeon (*Calœnas nicobarica*) from the Indian Archipelago, presented by Mr. Thomas H. Haynes; a Herring Gull (*Larus argentatus*), European, presented by Dr. E. H. Cree; a Bonnet Monkey (*Macacus sinicus* ♂) from India, deposited; a Rabbit-eared Perameles (*Perameles lagotis*) from West Australia, two Specious Pigeons (*Columba speciosa*) from South America, purchased; a Bennett's Wallaby (*Halmaturus bennetti* ♂) from Tasmania, received in exchange; a Wapiti Deer (*Cervus canadensis* ♂) born in the Gardens.

GEOGRAPHICAL NOTES

In *Petermann's Geographische Mittheilungen*, 1884, Heft iv., is an article on the island of São Thomé, accompanied by maps both of that island and of the neighbouring island of Rolas, by Prof. R. Greeff in Marburg. The contribution is the result of several months' residence on those islands in the course of a scientific tour through the islands of the Gulf of Guinea in 1879 and 1880. The map of the two islands in question is the united product of Prof. Greeff and of the proprietor of Rolas, Francisco José de Araujo: a map based partly on immediate exploration and observation, partly on careful information derived from natives. It both corrects and supplements in considerable measure the only two previous maps of St. Thomas known to the authors—that of 1829 by the English commander, T. Boteler, and that of 1844 by the Portuguese, Lopez de Lima. In the present map are entered for the first time the districts into which St. Thomas is divided, its "villas," its connecting highways, its more important plantations, and also the demarcation between the comparatively small cultivated part and the large wooded wilderness of the south and the interior. The map of Rolas is the first that has yet appeared of this island, which is intersected by the Equator. The history of St. Thomas is sketched from the year 1470, when it was discovered, without a single human inhabitant and almost wholly overgrown with forest, by the Portuguese sailors, João de Santarem and Pero de Escobar. Prof. Greeff calculates the dimensions of the island, which stretches ovally from 0° 2′ to 0° 30′ N. lat. and from 6° 34′ to 6° 54′ E. long., at about 52 kilometres by 34 kilometres, or altogether about 920 square kilometres.

Writing from Bakundu-ba-Nambeleh in October 1883, St. von Rogozinski gives an account of his travels between Cameroon and Calabar. On August 13 he left the coast in company with Clemens Tomczek, made his way up the Mungo for Bakundu, his other fellow-travellers being bound for the station of Mondoleh. On September 11 they determined on traversing the region of the Upper Mungo as far as its falls. Making their way through thick forest and over mountain chains, they came on Eliki, where were three rapids, and from which point the Mungo is no longer navigable. The land to the north-east gets even more elevated, and the path of the travellers became continually crossed by streams. At length, at 4° 46′ 15″ N. lat. and 9° 33′ 30″ E. long., they looked down from a hill on the sources of the Yabiang or Abo, a deep and "indescribably beautiful" valley clothed in the most exuberant tropical vegetation. The principal town here is Balombi-ba-Kange, built like all towns of that quarter in the form of a crescent or arch, with fetish houses in the middle. On September 14 they left Kange, and passed the slave town of Bakú. Further to the north they entered, the same day, the large town of Mokonje, the centre of the ivory trade for the lands of Biafra Bay. Next passing Bao, they reached Mambanda, close to the falls and the new lake, Balombi-ba-Mbu, they were in quest of, on the 16th. Quite exhausted, and finding their way further to the north rendered impossible by troops of elephants and the want of any guide that would venture, they were reluctantly obliged to fall back on the mission station of Bakundu, where Rogozinski was compelled to stay and nurse the wounds on his feet and ankles. On the 23rd Tomczek resumed alone the march northwards by a different route, and happily reached the lake M'Bu at half a day's marc. from Boa. The beautiful lake is four miles long, of round shape, inclosed by thickly-wooded hills, is deep, abounds in fishes, and receives on the west the river Soho, six or seven metres broad. Apparently it is of volcanic origin.

In a series of papers upon Early Discoveries in Australasia which Mr. E. A. Petherick, F.R.G.S., is contributing to the *Melbourne Review*, some curious and interesting facts are now made known for the first time, namely, the discovery of the west coast of Australia by the survivors of Magellan's expedition in 1522, the passage of Torres Straits by another Spanish vessel in 1545, sixty years before Torres, whose discovery and that of a Dutch vessel, the *Duyphen*, in the same year (1606) are hitherto the earliest authenticated accounts of the sighting of any part of the Australian coast by European vessels. But the most noteworthy statement Mr. Petherick makes is that the name of New Guinea belongs to that part of Australia now known as Queensland, and that the great island of Papua has borne the name of New Guinea erroneously for more than three centuries. Mr. Petherick is also able, from evidence upon a French *mappemonde* dated 1566, now in the Bibliothèque Nationale, Paris, to refute all claims to the discovery of Australia made at various times during the present and the last century on behalf of French navigators. Notwithstanding the early Spanish discoveries of Australia now referred to, Mr. Petherick asserts that the Portuguese were in the eastern seas twenty years earlier, and probably discovered Australia in the first decade of the sixteenth century.

Last autumn the expedition under Lieut. Holm for exploring the east coast of Greenland, and which is again to start northwards this spring, met a party of about sixty East-Greenlanders —men, women, and children—south of the island of Aluk, on the east coast. They were on the way to the west coast to sell bear-, fox-, and seal-skins. Every attempt was made by the Danish explorer to induce some of them to return and act as guides on his journey northwards, but the prospect of a visit to a Danish settlement proved too great. A considerable number of East-Greenlanders die on their way to the west coast. The East-Greenlanders are reported to differ much from the West-Greenlanders in stature and appearance, the men being often tall, with black beards and European cast of face. This seems to be particularly the case with those living far north. Both East- and West-Greenlanders have small hands and feet. During the year 1883 four boats with heathen East-Greenlanders arrived at Julianshaab. Three of these came from the distant Angmasalik, and in them there were also, for the first time, natives from Kelalualik, which is five days' journey further north. The latter stated that in the winter they were in the habit, when journeying on sleighs, of meeting with people living much further north. Kelalualik being situated, it is believed, between lat. 67° and 68° N., it may be assumed that the whole line of coast from lat. 65° to 70° is to some degree populated.

From the annual report of the Russian Geographical Society for 1883 we learn that the meteorological observations of the Novaya Zemlya Station are expected to be published in full in the course of this year, while the observers of the Sagastyr Meteorological Station, on the Lena, have remained there for a year longer. The publications of the Society, besides the *Izvestia* have been the following:—Prjevalsky's third journey to Central Asia, Potanin's sketches of North-Western Mongolia, Karelin's travels on the Caspian, and Maynoff's anthropology of the Morovinians. The next publications will contain: the report of Unkovsky's embassy to Kontaisha under Peter I., M. Sadovnikoff's folklore of Samara, the third volume of M. Potanin's work on Mongolia, a geological map of the shores of Lake Baikal, by M. Chersky, the remarkable collection of maps of the delta of the Amu-daria, by M. Kaulbars, and the concluding fascicule of the capital work of M. Semenoff, the "Geographical and Statistical Dictionary of Russia." The great gold medal has been awarded to M. Severtsoff for his explorations in Turkestan, and Count Lütke's medal to Prof. Wild for his labours in Russian meteorology, and for his work, "On the Temperature of the Air in Russia." The smaller gold medals were awarded to M. Lessar for his journeys, MM. Agapitoff and Khangaloff for their work on Shamanism in Siberia, M. Adrianoff for his journey to the Altay and Kuzuetzky Alatau, and M. Usoff, member of the West Siberian branch of the Society. Silver medals were awarded to Lieut. F. Schwatka and Mr. W. Hoffman, Secretary to the Anthropological Society of Washington; to MM. Andréeff, Grinevetsky, Konshin, Kosyakoff, Krivosheya, Kudryavtseff, Prince Urusbieff, Fuss, Wereschaghin, and Dobrotvorsky. The library has been increased by 4001 volumes.

THE MOVEMENTS OF THE EARTH[1]

IV.—*The Earth's Revolution*

It will be clear from what has gone before that the daily movement of the stars is an apparent one due to the real movement of the earth in an exactly opposite direction, and that the stars in the heavens appear to rise in the east and set in the west, because the earth rotates from west to east. And now comes this question: The period of twenty-four hours which is so familiar, and which is divided roughly into day and night, has apparently two perfectly different sides to it; for a certain period the stars are not seen at all in consequence of a body, which we call the sun, flooding the earth's atmosphere with its own tremendous light. Why should this be? In giving an answer to this question it is enough to say that the sun is a star so close to us, and so entirely outshining the other and more distant stars which are seen in the skies, that they seem to be things of a different order altogether. But they are not things of a different order, they are very much like our sun, and the different appearance is simply the result of the fact that the one is a star very near to us, whilst the others are suns inconceivably remote. In considering this apparent daily movement of the stars, and taking the sun into consideration, the fact is soon arrived at that the stars have another apparent movement differing somewhat from that one with which up to the present time we have alone been engaged. It has been said, and it is so obvious that it might almost have been left unsaid, that as a rule the stars are not seen when the sun is visible, so that the question whether the sun moves or appears to move among the stars must be attacked in a rather indirect manner. An observer on that part of the earth's surface directly under the sun sees it as at midday. Under these conditions the stars are of course not seen by him, but if he waited twelve sidereal hours, until that portion of the earth which he inhabited was opposite the sun's place, the stars would then be visible, and by noticing whether those seen by him each night were the same, he would be able to determine whether or not the sun moved or appeared to move among them. In one position of the sun it occupies that constellation of stars known as the Bull. These stars cannot then be seen, because the intense brilliancy of the sun puts them out, but with the sun in this position the group of stars known as the Scorpion is seen opposite at midnight. Then at a later period the sun gets into the constellation called the Crab, and we see at midnight no longer the Scorpion group but the group which is called the Goat. In this way it can be determined that the sun has an apparent movement among the stars, which is completed in a period which we call a year, at the end of which time the sun occupies the same position that it did a year previously, and the same group of stars is seen again in the south at midnight.

Not only, then, do the stars appear to make a complete revolution once a day, in consequence, as we have seen, of the earth's rotation, but once a year they also gradually change their apparent places, so that at the same hour each night different stars appear due south, thus indicating a movement of the sun among them.

The same difficulty that was met with before is again encountered here; is this movement of the sun among the stars a real or an apparent one? It is a question, however, which has been long since answered; and it can be very definitely stated, not only that the earth rotates on its axis in a period of twenty-four sidereal hours, but that it moves or revolves round the sun in a period which we call a year, and that it is this real movement which causes the apparent one of the sun among the stars. Let the reader take a top and spin it. Perhaps the top has a movement of progression as well as a movement of rotation, and it is in that way quite easy to see that the earth may rotate on its axis and revolve about the sun at one and the same time. And with a top of special construction its axis of rotation might be inclined so that its plane of rotation ceased to coincide with the plane of its motion of progression; still the two movements would go on, and in whatever position the top might be placed, its axis might be made to remain practically parallel to itself during its movements.

We may now, then, make the following statements:—*The earth revolves round the sun, and throughout the revolution the axis of rotation remains practically parallel to itself.* With regard to the latter part of this statement it may be added that if this were not so—if the axis of the earth were subject to perpetual change of direction—the declinations of the stars would also be subject to constant change.

[1] Continued from vol. xxix. p. 205.

The demonstration of this movement of the earth round the sun depends upon physical considerations in exactly the same way as does the demonstration of the earth's movement of rotation, and to these considerations attention must now be turned. It will be found that we have now to do with an entirely different branch of physics to that which we drew upon when seeking for a proof of the rotation. The utilisation of its principles for the purposes of astronomy is due to Dr. Bradley, a former Astronomer-Royal. In the year 1729 he made a series of observations of stars, expecting certain results to flow from them. Instead, however, of getting the results for which he had looked, his observations gave him some which differed entirely from his predicted ones, and which he failed to understand. For such a thing as this to happen is a piece of good fortune for the scientific investigator; it sets him thinking and working, and frequently leads him to the discovery of some hitherto unknown physical law. It set Dr. Bradley thinking and working. Curious as it may seem, the observation which led him to a complete understanding of this subject was what he observed one day when a boat at anchor near the shore at Greenwich began to get under weigh in a stiffish breeze. The little boat had one of those short pennants on its mast, and Dr. Bradley noticed that, as soon as the boat began to move, the direction of the wind, as indicated by the movements of this pennant, changed. Before proceeding to consider the bearing which this fact, seemingly remote from astronomy, has upon star work, it may be advisable

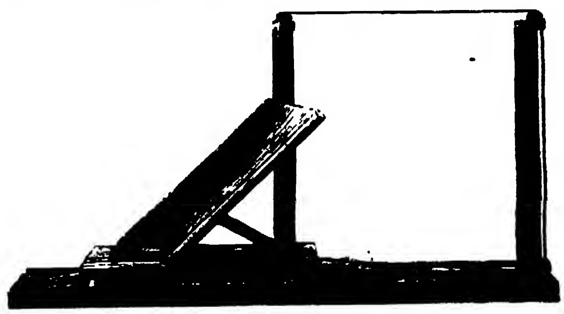


Fig. 35.—Model to illustrate the aberration of light. A square tube, with glass front and a slit along the centre of its upper side to allow the passage of a thread, is inclined at 45° and caused to run along a level track, while a weight suspended from a thread passing round three pulleys and attached at the other end to the front of the carriage is allowed to descend. In this figure the weight is at the commencement of its fall.

to take one or two simple illustrations which will show what must have passed through Bradley's mind as the explanation of the strange unexpected movements of the stars was slowly growing within it. The first illustration is one due to Sir George Airy. Suppose that a vessel is passing a fort, and that a shot is fired from the fort at the moving vessel. The shot will travel in a straight line; but it is evident that since the ship is moving, if that shot really pierces both sides of the vessel, then a line joining the spot where the ball pierced the one side to the spot where it pierced the other side will not be square to the direction of the ship's motion. During the short time taken by the shot to pass from one side of the ship to the other, the vessel has moved through a certain small distance, and if the line joining the two shot-holes were alone considered, it might be inferred that the shot had come from a direction in advance of the true one. That is one illustration, the point of it being that the motion of the vessel seems to have given a new direction to the shot. Take another illustration, more familiar, and perhaps almost as clear. In this country frequent opportunities offer themselves of travelling in cabs or railway trains, with the rain falling on their closed windows. Every one must have noticed that at such times there is always a very curious slant in the apparent direction of the drops whilst the train or the cab is in motion; the rain seems to come from a point in front of us; we always seem to meet the rain. The fact is that a body in motion, and especially a body with the velocity of an express train, does not receive the rain under the same conditions as when it is at rest. The question of its velocity has to be taken into consideration. An experiment will show better what is meant.

Imagine a weight supported by a piece of thread; the moment that thread is cut the weight falls in a straight line to the ground. If it be desired, therefore, to receive the falling weight in a tube at rest under the weight, and to so receive it that it shall not touch the sides of the tube as it passes through, the tube must be held in an upright position. Take another step, and suppose now that it is a question of causing the weight to fall through the tube whilst the tube itself is travelling at a certain rate, say at

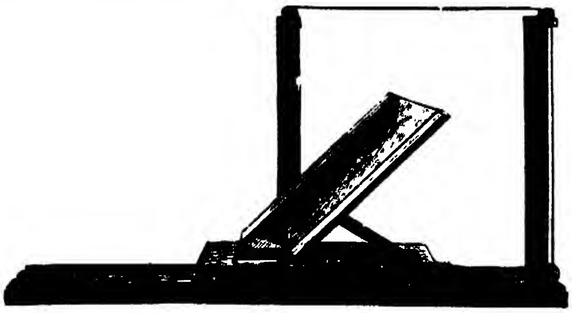

FIG. 36.—Same apparatus as preceding, but with the weight near the end of its fall.

the velocity of the falling weight. It is perfectly obvious that this cannot be done by holding the tube in a perpendicular position, the tube must be inclined, and the angle of its inclination will vary with the varying relative velocities of tube and weight. The more quickly the weight falls the less inclined must the tube be to receive it. This not only supplies the explanation of the slant of the rain on the windows of the railway carriage, but it explains what is very much more important from an astronomical point of view. Consider Fig. 37 for a moment. Here AB represents the path of anything falling, and *a*CB the angle of the tube destined to receive it. It may be called the angle of slant, but the point is not that we give it any particular name, but that its relation to the velocity of fall is a very fixed and definite one. Accept it as such, and then connect it,

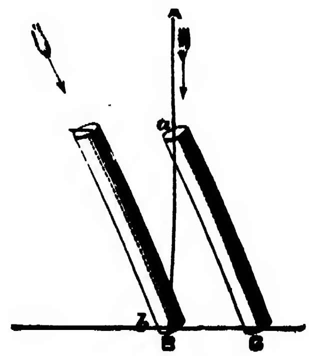

FIG. 37.

not with the falling weight or with the slant of the rain, but with the velocity of the light coming to the earth from any star in the heavens, and the velocity of the earth in its orbit round the sun.

It may be said that two assumptions are here made, first that light has a velocity, and secondly that the earth does move round the sun. Consider, then, the first of these, the question of the velocity of light. In our day, with all the experimental methods

FIG. 38.—Fizeau's mode of determining the velocity of light.

niceties which the labours of those who have gone before have placed at our disposal, this question of the velocity of light can be answered by what may be called a laboratory experiment. The first real attempt to answer the question was made some years ago by a Frenchman, M. Fizeau. His method of observation was a beautifully simple one, and has turned out to be highly satisfactory in its results. All the essential parts of his apparatus are shown in Fig. 38. Light from a lamp was made to pass through a system of lenses and was brought to a focus after reflection from the front surface of a piece of plain glass. The light was then grasped by an object-glass and sent out in a parallel beam to a station distant about five miles. There it fell on another object-glass, which again brought it to a focus on a mirror at the end of this second telescope. Then having got the light to the second mirror, it was reflected on its path back again. When the reflected light returned, part of it was allowed to go through the plain glass mirror to the eyepiece seen at the end of the telescope in Fig. 38. At the point where the rays crossed in the first telescope there was interposed the edge of a cogged wheel, to which a great velocity of rotation could be imparted by clockwork, and through the intervals between the teeth of which the light had to pass. Suppose first that the wheel is at rest. The lamp is lighted, and looking through the cogs of the wheel the observer sees the image of the lamp reflected back to him as a star of light from that distant

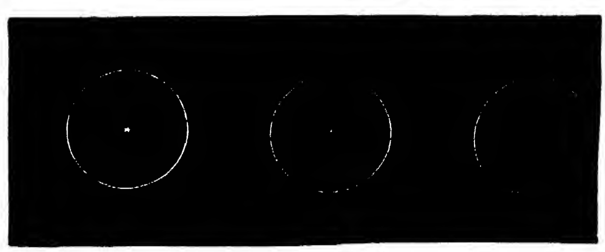

FIG. 39.—Fizeau's velocity of light apparatus. Appearance when the toothed wheel is at rest, when it is in slow motion, and when its rotation is so rapid as to cause complete extinction of the light.

mirror by means of the arrangement to which reference has been made.

Assume now that light occupies no time in travelling from the lamp to the first mirror, through the first telescope, across the space between the two telescopes, and back again after its reflection by the second mirror. Assume, in fact, that the velocity of light is infinite, then it is perfectly clear that an observer would keep on seeing that star of light whether the wheel remained at rest or were put in motion. But now assume that light does take a certain very small time to make the journey spoken of, and that the wheel can be turned with just such a velocity that when the light reaches it on its return it will meet, not an opening, but one of the cogs. Then the light would not be visible; it would find itself a cog behind, so that, if light travels very fast indeed and the wheel is made to travel with a great and known velocity and the relation existing between the velocities be known, the velocity of light can be measured in this way. That is the way in which Fizeau measured it, and he gave the velocity as being 190,000 miles per second.

It may be thought perhaps that this being the first attempt in a matter of this kind it was not very worthy of credit; but the similarity of the results which have been obtained in all such experiments proves that they are all very worthy of credit, and that this velocity must be accepted as established within narrow limits.

We come now to Foucault, the man to whose genius science owes the experimental proof of the earth's rotation, to which reference has already been made. He also attacked this question of the velocity of light. Going to work in quite a different way from Fizeau, he succeeded in enriching science with a method quite as reliable in its operation and as accurate in its results.

A pencil of light coming from a slit at S (see Fig. 40) impinges

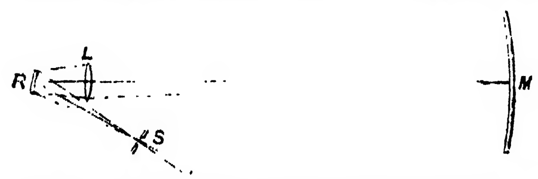

FIG. 40.—Foucault's arrangement for determining the velocity of light.

upon the plane mirror R, which is capable of turning round a vertical axis. This mirror reflects the light falling on its surface, and the action of the lens, L, causes an image to be formed on the surface of the concave mirror, M, the centre of which coincides with the axis at R. This concave mirror reflects the image backwards on its path to the slit. Foucault's arrangement, as has been said, was to have the mirror, R, made to rotate. If, therefore, R be turned about its axis while the light from the slit, S, is falling upon its surface, for so long as the light falls on the lens so long will the image of the slit be formed on the surface of the distant mirror. Similarly for so long as the reflected image falls upon the lens, so long will the image be reflected back to the slit. Now if the mirror were made to rotate rapidly, and light were infinite in its velocity, then once during each revolution of the mirror at one particular angle the light would be reflected back to the slit; but assume that light takes some very small fraction of time to travel over the space between the mirrors, it will be observed that the image will not be reflected back to the slit but will suffer a deflection in one direction or the other according as the mirror turns from left to right or from right to left, and, the velocity of the rotating mirror being known, the amount of this displacement will enable the velocity of light to be determined.

With two such different methods it might be supposed that the results obtained were very different. Not so, however; the velocity obtained by Fizeau was, as I have said, 190,000 miles per second, that by Foucault 185,000 per second.

It so happens that both these methods have been gone over quite recently, Fizeau's method by another Frenchman, M. Cornu, and Foucault's by Mr. Michelson, an officer in the American navy.

Mr. Michelson modified Foucault's method somewhat, the fault in which was that the displacement obtained was so extremely small, being but the fraction of a millimetre; and when it is remembered that the image is always more or less indistinct on account of atmospheric conditions and imperfection in the lenses and mirrors employed, it will be seen that it was difficult for Foucault to attain to any very great accuracy. Mr. Michelson therefore used an apparatus which would give him a greater deflection than that obtained by Foucault. As before, S (Fig. 41) was the slit, R the rotating mirror in the principal focus

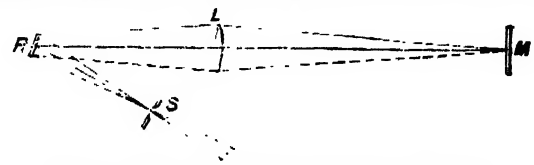

FIG. 41.—Michelson's variation of Foucault's experiment.

of the lens, but the distant mirror, instead of being concave, was a plane one, and the lens one of great focal length, for a reason that will appear immediately. This lens, in consequence of the smallness of its diameter in comparison with its great focal length, was not entirely convenient. In order that the displacement should be great, it is necessary that the distance between R and M, the distance from the revolving mirror to the slit, and the speed of rotation should be the greatest possible.

Unfortunately, the second condition clashes with the first,[1] for the distance from the revolving mirror to the slit, or the "radius" is the difference between the distances of principal and conjugate focus for the distant mirror M, and the greater the distance the smaller the radius. Two methods were employed by Mr. Michelson in overcoming this difficulty: first, he had his lens of great focal length, 150 feet, and he placed the revolving mirror, not at the principal focus, but fifteen feet within it. He thus managed to get a distance between the mirrors of 2000 feet with a radius of thirty feet, and his mirror made 256 revolutions per second. He then obtained a deflection of 133 millimetres, that being about 200 times greater than the deflection obtained by Foucault. This deflection he measured to within three or four hundredths of a millimetre in each observation.

Mr. Michelson's experiments were made along an almost level stretch of sea wall at the Naval Academy.

We are therefore justified in saying, as the result of these experiments of Fizeau and Cornu, Foucault and Michelson, that light has a velocity of some 186,000 miles per second.

If that be so, then, if the statement that the earth revolves about the sun be true, this must follow. In Fig. 42 *a, b, c, d*

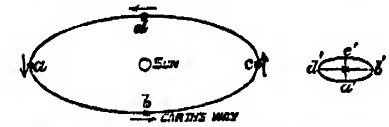

FIG. 42.—Annual change of a star's position, due to aberration: *a b c d*, the earth, in different parts of its orbit: *a' b' c' d'*, the corresponding aberration places of the star, varying from the true place in the direction of the earth's motion at the time.

represent the earth in different parts of its orbit around the sun; the contention is that if there be this revolution of the earth round the sun, and if light really travels with anything short of an infinite velocity, then the position of a star must change, for the reason that the telescope of the astronomer must always be pointed in advance of the star to catch its light in the same way that to catch the falling weight we had to incline the tube in the direction of its motion.

When any observation is made on any star in the heavens, the telescope of the astronomer must therefore be pointed in advance of the star to catch its light, and taking, as in the diagram, four different points in the earth's orbit, it is obvious that the telescope at these four different points must be pointed in four different directions with regard to the star. For instance, if we take a point at *c*, where the earth is travelling in the direction of the arrow, and the point at which the star would be seen if the earth were at rest, or the velocity of light were infinite, be indicated by the star in the figure, *c'* is the direction in which the star would be seen, and in which the astronomer's telescope must be pointed to catch its light. Similarly with the earth at *d* the telescope must be pointed to *d'*, and so with the earth at *a* we must have it pointing towards *a'*. It was this strange anomaly which puzzled Dr. Bradley in the year 1729.

[1] For full details of Michelson's experiments see NATURE, vol. xxi. p. 94 et seq.

He noticed that the stars moved in ellipses every year round a mean point. This fact of aberration, then, is a real thing. It has been said that the angle at which the tube had to be inclined to receive the weight depended upon their respective velocities, that the faster the tube travelled, the greater must be its inclination, and therefore the greater the angle the greater the earth's velocity with reference to the velocity of light. In the case of the majority of the stars what we get is an ellipse, and in an ellipse we have certain differences which have to be taken into account, the last difference of all being that an infinitely elongated ellipse is a straight line, and it is found that from one particular point of the heavens where, in consequence of this aberrational motion, the orbits of the stars round their mean places are almost circular, we at last get to a point where the motion is simply an oscillation of the star backwards and forwards to and from its mean place; we are dealing, in fact, with that form of the ellipse when it is in the form of a straight line. When we deal with an ellipse we no longer talk of the radius, but of the semi-axis major, which is half the greatest length. The angle of aberration of which I have spoken only amounts to 20"·4451, but though small, it is quite enough to prove that the earth does revolve, and that consequently the sun is the centre of the system to which the earth belongs. Now in order to show the importance of physical inquiry in this matter, there is another statement which must be made. If we consider this aberration question fully, we find in it what is perhaps the most perfect way of determining the distance of the sun from the earth, and it will be seen that it is perfectly simple, so simple in fact, that the wonder is that more attention has not been given to it in our text-books. We have first the fact that the inclination of the tube depends upon the relative velocities of the tube and falling body; in the case of light it will of course depend upon the relative velocities of the earth in its orbit and light radiating from a star. Knowing this latter to be somewhere about 186,000 miles per second, and the aberration angle to be 20" and something, we can get the relation of the earth's motion to the velocity of light, and it comes out to be about 1 to 10,089.

Now we know that the earth completes a revolution round the sun in 365¼ days. If it travelled with the velocity of light it would complete a revolution in 52m. 8·5s.

Again, we may say, and this is only a rough statement, that the radius of a circle is 1/6 of its circumference, so that if it took the earth fifty-two minutes to go round its circumference, or, as we call it, its orbit, it would take 1/6 of that time to go along the radius if it travelled with the velocity of light; it would therefore take 8m. 18s. But this radius is the distance of the earth from the sun, and having this time 8m. 18s., we have only to multiply the velocity of light[1] per second, by that, and we get 92,628,000 miles as the distance of the earth from the sun.

J. NORMAN LOCKYER

(*To be continued.*)

[1] The exact value is 186,380 miles according to Michelson, with a possible error of thirty-three miles.

THE ROYAL COMMISSION ON TECHNICAL INSTRUCTION

We have just received from the Commission the two volumes of their second Report on Technical Education. We give this week the Recommendations with which the Commissioners conclude their Report:—

Having carefully considered what is desirable and practicable in regard to the general and technical instruction of the various classes engaged in industrial pursuits in this country, we humbly offer the following recommendations, which require the intervention of the Legislature or of public departments:—

I. As to public elementary schools:

(*a*) That rudimentary drawing be incorporated with writing as a single elementary subject, and that instruction in elementary drawing be continued throughout the standards. That the inspectors of the Education Department, Whitehall, be responsible for the instruction in drawing. That drawing from casts and models be required as part of the work, and that modelling be encouraged by grant.

(*b*) That there be only two class subjects, instead of three, in the lower division of elementary schools, and that the object lessons for teaching elementary science shall include the subject of geography.

(*c*) That, after reasonable notice, a school shall not be deemed to be provided with proper "apparatus of elementary instruction" under Article 115 of the Code, unless it have a proper supply of casts and models for drawing.

(*d*) That proficiency in the use of tools for working in wood and iron be paid for as a "specific subject," arrangements being made for the work being done, so far as practicable, out of school hours. That special grants be made to schools in aid of collections of natural objects, casts, drawings, &c., suitable for school museums.

(*e*) That in rural schools instruction in the principles and facts of agriculture, after suitable introductory object lessons, shall be made obligatory in the upper standards.

(*f*) That the provision at present confined to Scotland, which prescribes that children under the age of fourteen shall not be allowed to work as full-timers in factories and workshops unless they have passed in the Fifth Standard, be extended to England and Wales.

II. As to classes under the Science and Art Department, and grants by the Department:

(*a*) That School Boards have power to establish, conduct, and contribute to the maintenance of classes for young persons and adults (being artisans) under the Science and Art Department. That in localities having no School Board the local authority have analogous powers.

(*b*) That the Science and Art Department shall arrange that the instruction in those science subjects which admit of it shall be of a more practical character than it is at present, especially in the "honours" stage; that payment on results be increased in the advanced stages of all subjects, at least to the level of those now made for practical chemistry and metallurgy, and that greater encouragement be given to grouping.

(*c*) That the examinations in agriculture be made to have a more practical bearing.

(*d*) That metallurgy, if it be retained, be divided into groups, as (1) the precious metals, (2) those extracted from metalliferous mines, as copper, tin, lead, &c., (3) iron and steel. That mining be similarly divided into (1) coal and (2) metalliferous mining.

(*e*) That the inspection of science classes by the Science and Art Department, with a view to ascertain the efficiency of the instruction, and of the apparatus and laboratories, be made more effective, with the assistance, where necessary, of local sub-inspectors.

(*f*) That it shall not be a requirement of the Science and Art Department that payment of fees be demanded from artisans for instruction in the science and art classes.

(*g*) That in the awards for industrial design more attention be paid by the Department, than is the case at present, to the applicability of the design to the material in which it is to be executed, and that special grants be made for the actual execution of designs under proper safeguards.

(*h*) That the limits of the building grants, under the Science and Art Department, to 500*l*. each for schools of Art and of Science should be abolished, and the conditions attached to them be revised.

(*i*) That, in addition to the loan of circulating collections and the grant of art reproductions at reduced cost, contributions be made to provincial industrial museums of original examples tending to advance the industries of the district in which such museums are situated.

III. Training Colleges for elementary teachers:

(*a*) That the teaching of science and art in Training Colleges, and its inspection by the Science and Art Department, be made efficient, and that arrangements be made for giving to selected students in those Colleges greater facilities and inducements for the study of art and science in the National Art Training School and the Normal School of Science at South Kensington, the Royal College of Science for Ireland, and other institutions of a similar class approved of by the Government.

IV. Secondary and technical instruction:

(*a*) That steps be taken to accelerate the application of ancient endowments, under amended schemes, to secondary and technical instruction.

(*b*) That provision be made by the Charity Commissioners for the establishment, in suitable localities, of schools, or departments of schools, in which the study of natural science, drawing, mathematics, and modern languages, shall take the place of Latin and Greek.

(*c*) That local authorities be empowered, if they think fit, to establish, maintain, and contribute to the establishment and

maintenance of secondary and technical (including agricultural) schools and colleges.

V. Public libraries and museums:

(*a*) That ratepayers have power, by vote, to sanction the increase of the expenditure, under the Public Libraries Acts, beyond its present limit, and that the restriction of the Acts to localities having 5,000 inhabitants and upwards be repealed.

(*b*) That museums of art and science and technological collections be opened to the public on Sundays.

VI. Special recommendations in regard to Ireland:

(*a*) That steps be taken at the earliest possible moment for the gradual introduction of compulsory attendance at elementary schools in Ireland.

(*b*) That payments be made by the National Board, under proper regulations, on the results of the teaching of home industries to children, young persons, and adults; as well as in aid of the salaries of industrial teachers.

(*c*) That systematic instruction be given to primary school teachers, qualifying them to teach the use of tools for working in wood and iron, in the primary schools.

(*d*) That steps be taken by the Commissioners of National Education in Ireland for the provision of books calculated to assist the teachers of primary schools in giving graduated lessons in rudimentary science.

(*e*) That grants-in-aid be sanctioned by the Treasury to approved agricultural schools, and to approved schools for instruction in local industries.

(*f*) That practical evening science classes for artisans form part of the instruction in the Royal College of Science of Ireland, in Dublin.

(*g*) That the Board of Intermediate Education take steps to insure the provision of adequate means for the practical teaching of science in the schools under their direction.

In addition to the preceding recommendations which necessitate action on the part of the Legislature or of the public authorities, or of both, your Commissioners make the following recommendations, requiring no such action, by way of suggestions for the consideration of those in whose power it is to comply with them:—

I. That it be made a condition by employers of young persons, and by the trade organisations, in the case of industries for which an acquaintance with science or art is desirable, that such young persons requiring it receive instruction therein either in schools attached to works or groups of works, or in such classes as may be available, the employers and trade organisations in the latter case contributing to the maintenance of such classes.

II. That the managers and promoters of science and technical classes should (*a*) so arrange the emoluments of teachers as to encourage them to retain their students for the advanced stages of subjects in which they have passed the elementary stage, and (*b*) that they should endeavour to group the teaching of cognate science subjects, as recommended by the Royal Commission on the Advancement of Science, and as provided for by the regulations of the Science and Art Department.

III. That scholarships be more liberally founded, especially for pupils of higher elementary schools, enabling them to proceed to higher technical schools and colleges.

IV. That the great national agricultural societies give aid to the establishment in counties of secondary schools or classes for teaching agriculture.

V. That those responsible for the management of primary schools in Ireland, in the districts where farming is defective, attach small example farms to such schools wherever it is possible; and that Boards of Guardians employ the plots of land attached to workhouses for the agricultural instruction of the children therein.

VI. That the subscriptions given by the liberality of the City of London and of the different Guilds, to the City and Guilds Institute, be made adequate to the fulfilment of the work which that Institute has undertaken, including the equipment and maintenance of its Central Institution.

In closing our Report we think it right to recall the fact that the first impulse to an inquiry into the subject of technical instruction was given by the important letter of Dr., now Sir Lyon, Playfair, K.C.B., of May 15, 1867, to the Chairman of the Schools' Inquiry Commission, in which he called attention to the great progress in engineering and manufactures abroad, shown at the Paris Exhibition of that year. In the course of our inquiry we have received much guidance from the letter on the subject by Mr. B. Samuelson, M.P., to the Vice-President of the Committee of Council on Education, dated November 16, 1867; from the Report of the Select Committee of the House of Commons on Scientific Instruction, 1868; the Report of the Royal Commission on the same subject; the papers by Mr. H. M. Felkin on Chemnitz, by Messrs. McLaren and Beaumont, and various other publications.

We desire also to express our thanks to the public authorities, to the owners and managers of industrial works, and to the numerous other persons, both at home and abroad, to whom we had occasion to apply for information, for the frank and courteous manner in which it was given to us; and also to acknowledge the prompt and valuable assistance which we received from the members of our Diplomatic and Consular services in the prosecution of our inquiry. All of which we humbly beg leave to submit for Your Majesty's gracious consideration.

ON THE NOMENCLATURE, ORIGIN, AND DISTRIBUTION OF DEEP-SEA DEPOSITS[1]

II.

Globigerina Ooze.—We designate by this name all those truly pelagic deposits containing over 40 per cent. of carbonate of lime, which consists principally of the dead shells of pelagic Foraminifera—*Globigerina*, *Orbulina*, *Pulvinulina*, *Pullenia*, *Sphæroidina*, &c. In some localities this deposit contains 95 per cent. of carbonate of lime. The colour is milky white, yellow, brown, or rose, the varieties of colour depending principally on the relative abundance in the deposit of the oxides of iron and manganese. This ooze is fine grained; in the tropics some of the Foraminifera shells are macroscopic. When dried it is pulverulent. Analyses show that the sediment contains, in addition to carbonate of lime, phosphate and sulphate of lime, carbonate of magnesia, oxides of iron and manganese, and argillaceous matters. The *residue* is of a reddish brown tinge. Lapilli, pumice, and glassy fragments, often altered into palagonite, seem always to be present, and are frequently very abundant. The mineral particles are generally angular, and rarely exceed 0·08 mm. in diameter; monoclinic and triclinic feldspars, augite, olivine, hornblende, and magnetite are the most frequent. When quartz is present, it is in the form of minute, rounded, probably wind-borne grains, often partially covered with oxide of iron. More rarely we have white and black mica, bronzite, actinolite, chromite, glauconite, and cosmic dust. Silliceous organisms are probably never absent, sometimes forming 20 per cent. of the deposit, at other times only recognisable after careful microscopic examination. In some regions the frustules of Diatoms predominate, in others the skeletons of Radiolarians.

The *fine washings*, viewed with the microscope, are not homogeneous. The greater part consists of argillaceous matter coloured by the oxides of iron and manganese. Mixed with this, we distinguish fragments of minerals with a diameter less than 0·05 mm., and minute particles of pumice can nearly always be detected. Fragments of Radiolarians, Diatoms, and siliceous spicules can always be recognised, and are sometimes very abundant.

Pteropod Ooze.—This deposit differs in no way from a Globigerina ooze except in the presence of a greater number and variety of pelagic organisms, and especially in the presence of Pteropod and Heteropod shells, such as *Diacria*, *Atlanta*, *Styliola*, *Carinaria*, &c. The shells of the more delicate species of pelagic Foraminifera and young shells are also more abundant in these deposits than in a Globigerina ooze. It must be remembered that the name "Pteropod ooze" is not intended to indicate that the deposit is chiefly composed of the shells of these mollusks, but, as their presence in a deposit is characteristic and has an important bearing on geographical and bathymetrical distribution, we think it desirable to emphasise the presence of these shells in any great abundance. It may here be pointed out that there is a very considerable difference between a Globigerina

[1] A Paper read before the Royal Society of Edinburgh by John Murray and [illegible]enard. Communicated by John Murray. Continued from p. 88.

ooze or a Pteropod ooze situated near continental shores and deposits bearing the same names situated towards the centres of oceanic areas, both with respect to mineral particles and remains of organisms.

Diatom Ooze.—This ooze is of a pale straw colour, and is composed principally of the frustules of Diatoms. When dry it is a dirty white siliceous flour, soft to the touch, taking the impression of the fingers, and contains gritty particles which can be recognised by the touch. It contains on an average about 25 per cent. of carbonate of lime, which exists in the deposit in the form of small *Globigerina* shells, fragments of Echinoderms and other organisms. The *residue* is pale white and slightly plastic; minerals and fragments of rocks are in some cases abundant; these are volcanic, or, more frequently, fragments and minerals coming from continental rocks and transported by glaciers. The *fine washings* consist essentially of particles of Diatoms along with argillaceous and other amorphous matter. We estimate that the frustules of Diatoms and skeletons of siliceous organisms make up more than 50 per cent. of this deposit.

Radiolarian Ooze.—It was stated, when describing a Globigerina ooze, that Radiolarians were seldom, if ever, completely absent from marine deposits. In some regions they make up a considerable portion of a Globigerina ooze, and are also found in Diatom ooze and in the terrigenous deposits of the deeper water surrounding the land. In some regions of the Pacific, however, the skeletons of these organisms make up the principal part of the deposits, and to these we have given the name "Radiolarian ooze." The colour is reddish or deep brown, due to the presence of the oxides of iron and manganese. The *mineral particles* consist of fragments of pumice, lapilli, and volcanic minerals, rarely exceeding 0·07 mm. in diameter. There is not a trace of carbonate of lime in the form of shells in some samples of Radiolarian ooze, but other specimens contain 20 per cent. of carbonate of lime derived from the shells of pelagic Foraminifera. The clayey matter and mineral particles in this ooze are the same as those found in the red clays, which we will now proceed to describe.

Red Clay.—Of all the deep-sea deposits this is the one which is distributed over the largest areas in the modern oceans. It might be said that it exists everywhere in the abysmal regions of the ocean basins, for the *residue* in the organic deposits which has been described under the names Globigerina, Pteropod, and Radiolarian ooze, is nothing else than the red clay. However, this deposit only appears in its characteristic form in those areas where the terrigenous minerals and calcareous and siliceous organisms disappear to a greater or less extent from the bottom. It is in the central regions of the Pacific that we meet with the typical examples. Like other marine deposits, this one passes laterally, according to position and depth, into the adjacent kind of deep-sea ooze or mud.

The argillaceous matters are of a more or less deep brown tint from the presence of the oxides of iron and manganese. In the typical examples no mineralogical species can be distinguished by the naked eye, for the grains are exceedingly fine and of nearly uniform dimensions, rarely exceeding 0·05 mm. in diameter. It is plastic and greasy to the touch; when dried it coagulates into lumps so coherent that considerable force must be employed to break them. It gives the brilliant streak of clay, and breaks down in water. The pyrognostic properties show that we are not dealing with a pure clay, for it fuses easily before the blowpipe into a magnetic bead.

Under the term red clay are comprised those deposits in which the characters of clay are not well pronounced, but which are mainly composed of minute particles of pumice and other volcanic material which, owing to their relatively recent deposition, have not undergone great alteration. If we calculate the analyses of red clay, it will be seen, moreover, that the silicate of alumina present as clay ($2SiO_2, Al_2O_3 + 2H_2O$) comprises only a relatively small portion of the sediment; the calculation shows always an excess of free silica, which is attributed chiefly to the presence of siliceous organisms.

Microscopic examination shows that a red clay consists of argillaceous matter, minute mineral particles, and fragments of siliceous organisms; in a word, it is in all respects identical with the *residue* of the organic oozes. The mineral particles are for the greater part of volcanic origin, except in those cases where continental matters are transported by floating ice, or where the sand of deserts has been carried to great distances by winds. These volcanic minerals are the same constituent minerals of modern eruptive rocks, enumerated in the description of volcanic muds and sands; in the great majority of cases they are accompanied by fragments of lapilli and of pumice more or less altered. Vitreous volcanic matters belonging to the acid and basic series of rocks predominate in the regions where the red clay has its greatest development, and it will be seen presently that the most characteristic decompositions which there take place are associated with pyroxenic lavas.

Associated with the red clay are almost always found concretions and microscopic particles of the oxides of iron and manganese, to which the deposit owes its colour. Again, in the typical examples of the deposit, zeolites in the form of crystals and crystalline spherules are present, along with metallic globules and silicates which are regarded as of cosmic origin. Calcareous organisms are so generally absent in the red clay that they cannot be regarded as characteristic; when present, they are chiefly the shells of pelagic Foraminifera, and are usually met with in greater numbers in the surface-layers of the deposit, to which they give a lighter colour. On the other hand, the remains of Diatoms, Radiolarians, and Sponge-spicules are generally present, and are sometimes very abundant. The ear-bones of various Cetaceans, as well as the remnants of other Cetacean bones, and the teeth of sharks, are, in some of the typical samples far removed from the continents, exceedingly abundant, and are often deeply impregnated with, or embedded in thick coatings of, oxides of iron and manganese. The remains of these Vertebrates have seldom been dredged in the organic oozes, and still more rarely in the terrigenous deposits.

The *fine washings*, as examined with a power of 450 diameters, are composed of an amorphous matter, fragments of minerals, the remains of siliceous organisms, and colouring substances. What we call amorphous matter may be considered as properly the argillaceous matter, and presents characters essentially vague. It appears as a gelatinous substance, without definite contours, generally colourless, perfectly isotropic, and forms the base which agglutinates the other particles of the washings. As these physical properties are very indefinite, it is difficult to estimate even approximately the quantity present in a deposit. However, it augments in proportion as the deposit becomes more clayey, but we think that only a small quantity of this substance is necessary to give a clayey character to a deposit. Irregular fragments of minerals, small pieces of vitreous rocks, and remains of siliceous organisms predominate in this fundamental base. These particles probably make up about 50 per cent. of the whole mass of the *fine washings*, and this large percentage of foreign substances must necessarily mask the character of the clayey matter in which they are embedded. The mineral particles are seldom larger than 0·01 mm. in diameter, but descend from this size to the merest points. It is impossible, on account of their minuteness, to say to what mineral species they belong: their optical reactions are insensible, their outlines too irregular, and all special coloration has disappeared. All that can be reasonably said is that these minute mineral particles probably belong to the same species as the larger particles in the same deposit, such as feldspar, hornblende, magnetite, &c. In the case of pumice and siliceous organisms the fragments can, owing to their structure, be recognised when of a much less size than in the case of the above minerals.

It can be made out by means of the microscope that the colouring substances are hydrated oxides of iron and manganese. The former is scattered through the mass in a state of very fine division; in some points, however, it is more localised, the argillaceous matter here appearing with a browner tinge, but these spots are noticed gradually to disappear in the surrounding mass. The coloration given by the manganese is much more distinct; there are small, rounded, brownish spots with a diameter of less than 0·01 mm., which disappear under the action of hydrochloric acid with disengagement of chlorine. These small round concretions, which are probably a mixture of the oxides of iron and manganese, will be described with more detail in the *Challenger* Report.

The following table shows the nomenclature we have adopted:—

Terrigenous deposits.	Shore formations, Blue mud, Green mud and sand, Red mud,	Found in inland seas and along the shores of continents.
	Coral mud and sand, Coralline mud and sand, Volcanic mud and sand,	Found about oceanic islands and along the shores of continents.

Pelagic deposits.	Red clay, Globigerina ooze, Pteropod ooze, Diatom ooze, Radiolarian ooze,	Found in the abysmal regions of the ocean basins.

Geographical and Bathymetrical Distribution.—In the preceding pages we have confined our remarks essentially to the lithological nature of the deep-sea deposits, including in this term the dead shells and skeletons of organisms. From this point of view it has been possible to define the sediments and to give them distinctive names. We now proceed to consider their geographical and bathymetrical distribution, and the relations which exist between the mineralogical and organic composition and the different areas of the ocean in which they are formed.

A cursory glance at the geographical distribution shows that the deposits which we have designated MUDS and SANDS are situated at various depths at no great distance from the land, while the ORGANIC OOZES and RED CLAYS occupy the abysmal regions of the ocean basins far from land. Leaving out of view the coral and volcanic muds and sands which are found principally around oceanic islands, we notice that our blue muds, green muds and sands, red muds, together with all the coast and shore formations, are situated along the margins of the continents and in inclosed and partially inclosed seas. The chief characteristic of these deposits is the presence in them of continental debris. The blue muds are found in all the deeper parts of the regions just indicated, and especially near the embouchures of rivers. Red muds do not differ much from blue muds except in colour, due to the presence of ferruginous matter in great abundance, and we find them under the same conditions as the blue muds. The green muds and sands occupy, as a rule, portions of the coast where detrital matter from rivers is not, apparently, accumulating at a rapid rate, viz. on such places as the Agulhas Bank, off the east coast of Australia, off the coast of Spain, and at various points along the coast of America.

Let us cast a glance at the region occupied by terrigenous deposits, in which we include all truly littoral formations. This region extends from high-water mark down, it may be, to a depth of over four miles, and in a horizontal direction from 60 to perhaps 300 miles seawards, and includes, in the view we take, all inland seas, such as the North Sea, Norwegian Sea, Mediterranean Sea, Red Sea, China Sea, Japan Sea, Caribbean Sea, and many others. It is the region of change and of variety with respect to light, temperature, motion, and biological conditions. In the surface waters the temperature ranges from 80° F. in the tropics, to 28° F. in the polar regions. Below the surface down to the nearly ice-cold water found at the lower limits of the region in the deep sea, there is in the tropics an equally great range of temperature. Plants and animals are abundant near the shore, and animals extend in relatively great abundance down to the lower limits of this region which is now covered by these terrigenous deposits. The specific gravity of the water varies much, owing to mixture with river water or great local evaporation, and this variation in its turn affects the fauna and flora. In the terrigenous region tides and currents produce their maximum effect, and these influences can in some instances be traced to a depth of 300 fathoms, or nearly 2000 feet. The upper or continental margin of the region is clearly defined by the high-water mark of the coast-line, which is constantly changing through breaker action, elevation, and subsidence. The lower or abysmal margin is less clearly marked out. It passes in most cases insensibly into the abysmal region, but may be regarded as ending when the mineral particles from the neighbouring continents begin to disappear from the deposits, which then pass into an organic ooze or a red clay.

Contrast with these, those conditions which prevail in the abysmal region in which occur the organic oozes and red clay, the distribution of which will presently be considered. This area comprises vast undulating plains from two to five miles beneath the surface of the sea, the average being about three miles, here and there interrupted by huge volcanic cones (the oceanic islands). No sunlight ever reaches these deep cold tracts. The range of temperature over them is not more than 7°, viz. from 31° to 38° F., and is apparently constant throughout the whole year in each locality. Plant life is absent, and although animals belonging to all the great types are present, there is no great variety of form or abundance of individuals. Change of any kind is exceedingly slow.

What is the distribution of deposits in this abysmal region of the earth's surface? In the tropical and temperate zones of the great oceans, which occupy about 110° of latitude between the two polar zones, at depths where the action of the waves is not felt, and at points to which the terrigenous materials do not extend, there are now forming vast accumulations of *Globigerina* and other pelagic Foraminifera, coccoliths, rhabdoliths, shells of pelagic Mollusks, and remains of other organisms. These deposits may perhaps be called the sediments of median depths and of warmer zones, because they diminish in great depths and tend to disappear towards the poles. This fact is evidently in relation with the surface temperature of the ocean, and shows that pelagic Foraminifera and Mollusks live in the superficial waters of the sea, whence their dead shells fall to the bottom. Globigerina ooze is not found in inclosed seas nor in polar latitudes. In the Southern Hemisphere it has not been met with beyond the 50th parallel. In the Atlantic it is deposited upon the bottom at a very high latitude below the warm waters of the Gulf Stream, and is not observed under the cold descending polar current which runs south in the same latitude. These facts are readily explained, if we admit that this ooze is formed chiefly by the shells of surface organisms, which require an elevated temperature and a wide expanse of sea. But as long as the conditions of the surface are the same, we would expect the deposits at the bottom also to remain the same. In showing that such is not the case, we are led to take into account an agent which is in direct correlation with the depth. We may regard it as established that the majority of the calcareous organisms which make up the Globigerina and Pteropod oozes live in the surface waters, and we may also take for granted that there is always a specific identity between the calcareous organisms which live at the surface and the shells of these pelagic creatures found at the bottom. This observation will permit us to place in relation the organic deposits and those which are directly or indirectly the result of the chemical activity of the ocean. Globigerina ooze is found in the tropical zone at depths which do not exceed 2400 fathoms, but when depths of 3000 fathoms are explored in this zone of the Atlantic and Pacific, there is found an argillaceous deposit without, in many instances, any trace of calcareous organisms. When we descend from the "submarine plateaus" to depths which exceed 2250 fathoms, the Globigerina ooze gradually disappears, passing into a grayish marl, and finally is wholly replaced by an argillaceous material which covers the bottom at all depths greater than 2900 fathoms.

The transition between the calcareous formations and the argillaceous ones takes place by almost insensible degrees. The thinner and more delicate shells disappear first. The thicker and larger shells lose little by little the sharpness of their contour and appear to undergo a profound alteration. They assume a brownish colour, and break up in proportion as the calcareous constituent disappears. The red clay predominates more and more as the calcareous element diminishes in the deposit.

If we now recollect that the most important elements of the organic deposits have descended from the superficial waters, and that the variations in contour of the bottom of the sea cannot of themselves prevent the debris of animals and plants from accumulating upon the bottom, their absence in the red clay areas can only be explained by a decomposition under the action of a cause which we must seek to discover.

Pteropod ooze, it will be remembered, is a calcareous organic deposit, in which the remains of Pteropods and other pelagic Mollusca are present, though they do not always form a preponderating constituent, and it has been found that their presence is in correlation with the bathymetrical distribution.

In studying the nature of the calcareous elements which are deposited in the pelagic areas, it has been noticed that, like the shells of the Foraminifera, those of the Thecosomatous Pteropoda, which live everywhere in the superficial waters, especially in the tropics, become fewer in number as the depth from which the sediments are derived increases. We have just observed that the shells of Foraminifera disappear gradually as we descend along a series of soundings from a point where the Globigerina ooze has abundance of carbonate of lime, towards deeper regions; but we notice also that when the sounding-rod brings up a graduated series of sediments from a declivity descending into deep water, among the calcareous shells those of the Pteropods and Heteropods disappear first in proportion as the depth increases. At depths less than 1400 fathoms in the tropics a Pteropod ooze is found with abundant remains of Heteropods and Pteropods; deeper soundings then give a Globigerina ooze without these molluscan remains; and in still greater depths, as before men-

tioned, there is a red clay in which calcareous organisms are nearly, if not quite, absent.

In this manner, then, it is shown that the remains of calcareous organisms are completely eliminated in the greatest depths of the ocean. For if such be not the case, why do we find all these shells at the bottom in the shallower depths, and not at all in the greater depths, although they are equally abundant on the surface at both places? There is reason to think that this solution of calcareous shells is due to the presence of carbonic acid throughout all depths of ocean water. It is well known that this substance, dissolved in water, is an energetic solvent of calcareous matter. The investigations of Buchanan and Dittmar have shown that carbonic acid exists in a free state in sea water, and in the second place, Dittmar's analyses show that deep-sea water contains more lime than surface water. This is a confirmation of the theory which regards carbonic acid as the agent concerned in the total or partial solution of the surface shells before or immediately after they reach the bottom of the ocean, and is likewise in relation with the fact that in high latitudes where fewer calcareous organisms are found at the surface, their remains are removed at lesser depths than where these organisms are in greater abundance. It is not improbable that sea water itself may have some effect in the solution of carbonate of lime, and further, that the immense pressure to which water is subjected in great depths may have an influence on its chemical activity. We await the result of further researches on this point, which have been undertaken in connection with the *Challenger* Reports. We are aware that objections have been raised to the explanation here advanced, on account of the alkalinity of sea water, but we may remark that alkalinity presents no difficulty which need be here considered (Dittmar, "Phys. Chem. *Chall.* Exp.," part i. 1884).

This interpretation permits us to explain how the remains of Diatoms and Radiolarians (surface organisms like the Foraminifera) are found in greater abundance in the red clay than in a Globigerina ooze. The action which suffices to dissolve the calcareous matter has little or no effect upon the silica, and so the siliceous shells accumulate. Nor is this view of the case opposed to the distribution of the Pteropod ooze. At first we should expect that the Foraminifera shells, being smaller, would disappear from a deposit before the Pteropod shells; but if we remember that the latter are very thin and delicate, and, for the quantity of carbonate of lime present, offer a larger surface to the action of the solvent than the thicker, though smaller, Globigerina shells, we shall see the explanation of this apparent anomaly.

(To be continued.)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The Special Board for Mathematics has reported in favour of an interval of one year being allowed between the second and the third parts of the Mathematical Tripos, instead of seven months as at present. It is also suggested that the work done in the first two parts of the Tripos has deteriorated in consequence of being held in the latter part of the Easter Term, when men are subject to many distractions.

The new buildings for the Department of Practical Botany are to be proceeded with forthwith, and thus Dr. Vines will gain the much-needed accommodation he has so long waited for.

The thanks of the University have been voted to Sir A. Gordon and to Mr. A. P. Maudslay for their presents of valuable ethnological collections, made by them in Fiji, to the new Museum of Archæology.

The eighteenth annual report of the Museums and Lecture-Rooms Syndicate draws attention to the pressing need of additional accommodation for Human and Comparative Anatomy and for Physiology. Nothing can be done to enlarge the provision of Human Anatomy till the new Chemical Laboratory is completed. A further report as to the accommodation for Physiology and Comparative Anatomy will be made shortly.

Profs. Liveing and Dewar report that additional special courses for medical students have been established. Lord Rayleigh reports that the elementary demonstrations on Physics in the Cavendish Laboratory are attended by forty students, the advanced by twenty, and the professorial lectures by from twenty to thirty students. Numerous additions of physical apparatus have been made during the year.

Prof. Lewis records a continued improvement in the Mineralogical Museum. Prof. J. P. Cooke of Harvard has presented a large and fine series of American specimens. Mr. G. Seligman of Coblentz has sent specimens far exceeding in value those for which they were exchanged. Mr. Solly brought back many excellent specimens from a tour in Norway; and the late Mr. Tawney's polariscope and optic sections have been presented by his brother.

Prof. Stuart has added some large machines to the Mechanical Department. There were sixty-one pupils in the Lent Term, and their work continues to improve. He states that Mr. Lyon's services are of extreme value as superintendent of the workshops, for he combines practical experience and theoretical knowledge in a manner rarely to be met with.

The additions to the Woodwardian Museum include twelve or fourteen thousand specimens, the collection of the late Mr. Montagu Smith, B.A., of Trinity College, a promising young student of geology, given by his parents in fulfilment of his expressed wish. They include several thousand specimens from all the crags of Norfolk and Suffolk, a rich collection of Chalk mollusca from Berkshire, mollusca from the Gault of Folkestone, the Farringdon sponge-bed, and specimens from many Jurassic localities. Mammalian remains from the Hamstead Beds, Isle of Wight, and Vertebrates from the Gault of Folkestone have been purchased. A number of interesting specimens from the Welsh Palæozoic strata, from Lower Llandoveny down to Harlech, have been added by Mr. T. Roberts. The Library continues to increase largely.

Mr. J. W. Clark reports that the collection acquired from Dr. Dohrn, exhibited at the Fisheries Exhibition, turns out much more valuable than was anticipated, there being 283 species of Invertebrates, and 38 of fishes in it, each being usually represented by several specimens. All are in first-rate order, and exceptionally good specimens. Mr. H. B. Brady has announced his intention of presenting all his valuable collections of Rhizopoda, chiefly Foraminifera, to be forwarded as the monographs relating to them are completed. Large instalments have already arrived, including the collection of British brackish-water and estuarine forms described in *Ann. and Mag. Nat. Hist.*, 1870, the North Polar Foraminifera from the Nares Expedition, the Carboniferous and Permian Foraminifera ("Pal. Soc. Monograph"), a large series of the genus Fusulina, a collection of the genera Nummulites and Orbiloides, numerous specimens of Loftusia and Parkeria, Nummulites from Egypt, and microzoic rocks illustrating the extent to which Forominifera are concerned in the building of geological strata.

Mr. Cooke, Curator in Zoology, has catalogued and arranged the specimens of Murex, Purpura, Triton, Fasciolaria, Buccinum, Nassa, Fusus, Voluta, and Mitra, and related genera.

Mr. Hans Gadow, Strickland Curator, has been occupied in arranging the collection of birds' skins in a systematic way, and preparing to exhibit the groups in a complete manner, skins, skeletons, viscera, nests, and eggs, in juxtaposition, but want of space, cases and drawers, is a great hindrance. Valuable donations of birds' skins have been received from Major H. W. Feilden (Natal), Lady Barkly (Penang), and Mr. C. E. Lister (St. Vincent, Antilles), and in exchange from the Australian Museum, Sydney (New Guinea species).

The Morphological Department records good progress; many diagrams and models have been added owing to the liberality of Trinity College, and much valuable material has been brought by students who have visited foreign countries for purposes of morphological research. The Balfour Library is of great value, and Mr. A. J. Balfour, M.P., is defraying the cost of continuing the periodicals. Twelve students have been engaged in research; seventeen have worked in the advanced class; forty-four worked at embryology last year, while nearly fifty have worked at Elementary Morphology during the past winter. Overwhelming pressure has been put upon the department owing to the new arrangements for Elementary Biology in the M.B. examinations; 201 students entered it last term, belonging to more than one year, and no lecture-room or work-room has proved adequate for them all. The work of research, storage of material, and administration of classes are much interfered with by want of suitable rooms, and new rooms are urgently needed. A bust of Prof. Balfour, executed in bronze by Hildebrandt of Florence, has been presented to the Laboratory by Prof. Darwin and Mr. J. W. Clark.

Prof. Michael Foster reports that the teaching of Physiology has been still further developed, but has suffered somewhat from the necessary use of the Laboratory by the class of Elementary

Biology. The generous gift by an anonymous donor of 500*l.* towards new apparatus has been a great boon. A gas-engine and many valuable pieces of apparatus have been added.

Prof. Macalister states that the number of students dissecting has been nearly one hundred, and a still larger number attended the lectures on Human Anatomy. Many important specimens have been presented to the Museum of Human Anatomy by Prof. Macalister.

The Philosophical Library is increasingly used, and many valuable donations of books have been received by Mr. J. W. Clark, Prof. Humphry, Prof. Babington, Mr. D. McAlister, and Mr. Pitman of Bath.

SCIENTIFIC SERIALS

American Journal of Science, May 1884.—Remarks on Prof. Newcomb's "Rejoinder," in connection with his review of "Climate and Time," by Dr. James Croll.—Communications from the United States Geological Survey, Rocky Mountain Division, VI.—On an interesting variety of Löllingite and other minerals (one illustration), by W. F. Hillebrand. Amongst the ores analysed by the author there is one from the Missouri Mine, Park County, Colorado, which he thinks may probably be a new mineral. It is composed largely of a sulphobismuthite of copper and silver, and occurs in a quartz gangue associated with chalcopyrite and wolframite.—Notes on American earthquakes, with tabulated record of seismic disturbances in every part of the continent during the year 1883, by Prof. C. G. Rockwood.—Thermometer exposure, by H. A. Hazen. The paper is chiefly occupied with questions relating to the locality in large regions where the thermometer should be exposed in order to obtain the most trustworthy results, and to the immediate environment of the thermometer best calculated to fulfil the same requirement. There are several comparative tables of results obtained with various instruments under varying conditions of time, aspect, and altitude.—Hillocks of angular gravel and disturbed stratification associated with glacial phenomena (four illustrations), by T. C. Chamberlain. The paper deals especially with the kames or eskers analogous to the osars of Sweden, occurring in various parts of New Hampshire, Massachusetts, New York, and Wisconsin. The author infers from their inherent characteristics and their association with morainic belts, that the gravel hills in question were formed, not by beach action, but by numerous marginal streams along the edge of the great ice sheet during the Glacial period.—Extinct glaciers of the San Juan Mountains, Colorado, by R. C. Hills.—On the gender of names of varieties and subspecies in botanical nomenclature, by Asa Gray.—On secondary enlargements of feldspar fragments in certain Keweenawan sandstones (four illustrations), by C. A. Vanhise.—Principal characters of American cretaceous Pterodactyls, part i., the skull of Pteranodon (with plate), by Prof. O. C. Marsh. The skull of these Pterodactyls from the Middle Chalk, West Kansas, is described as differing from that of other known Pterosauria in the absence of teeth and of anterior nasal apertures distinct from the antorbital openings; in the presence of the elongated occipital crest; lastly, in the whole jaws, which appear to have been covered with a horny sheath, as in recent birds. All belong to the genus Pteranodon, some of the species of which were of prodigious size, with a spread of wings of about twenty-five feet. Remains of over six hundred individuals are now in the museum of Yale College.

Journal of the Russian Chemical and Physical Society, vol. xvi., fasc. 2.—On the action of the bromide of aluminium on ethylene and on the bromides of saturated hydrocarbons, by M. Gustavson.—On the specific heat of solutions, and on the thermal effects at their formation, by W. Alexeyeff. Submitting to a closer investigation those solutions which are accompanied by a lowering of temperature, the author comes to the conclusion that such is the case for those liquids which have not a chemical affinity, and that those are true solutions; while in those cases where a rise of temperature is noticed, the dissolved liquid enters into chemical combination with the dissolving one. He makes a series of very interesting experiments in order to determine the thermal effects of various solutions.—On the relations between the chemical composition and the refractive power of chemical compounds, by J. Kanonnikoff (second paper).—On the structure of nitro-compounds of the saturated series, by J. Kissel.—On the composition of the mineral waters of Caucasus, by J. Barsilovsky.—On the structure of the blue indigo, by P. Alexeyeff.—On the action of alkalies on chondrine, by M. Schwarz.—On the azocuminic acid, by P. Alexeyeff (first paper).—On chemical affinity, by A. Bazaroff.—Analysis of the epidermis attacked by the *Prosyarsis rubra*, by K. Wagner.—On the preparation of pure albumin, and on the determination of chlorine in urine, by W. Mikhailoff.—On the structure of the atmosphere and on the general laws of the theory of gases, by E. Rogovsky. The strong mathematical inquiry of the author brings him to the following conclusions:—However the atmosphere has no limits, but at a height of 1000 km. the density of air is very near to zero; its constitution varies with the height, the content of oxygen decreasing as the height increases; this change is very slow for heights less than 10,000 m., still it might be ascertained by accurate measurements; for heights less than 10,000 m. the density of air can be calculated as if it were a simple gas; the decrease of density with the height goes on slower when the temperature at the surface of the earth is higher. The paper has to be continued.—On the theory of measurements, by N. Sloughinoff.—On galvanic batteries, by P. Novikoff.

Rivista Scientifico-Industriale, March 31 and April 15.—Electric currents through contact with earth, by Prof. A. Volta.—Experiments with electrified paper, by D. Surdi.—Variations in the electric resistance of solid and pure metallic wires, with variations of temperature, by Prof. Angelo Emo.—On the Gauthier and Walrand methods of distinguishing steel from iron, by the editor.—Note on two hybrids of *Anas boschas* and *Dafila acuta*, by Dante Roster.

Rendiconti del R. Istituto Lombardo, April 3 and 17.—Programme of prize essays in various departments of Science, Art, and Letters proposed for the years 1884–91.—The Castle of Milan, its historic and artistic associations, by Prof. Giuseppe Mongeri.—On some unpublished fragments of Anatolius's Greek version of the "Codex Justinianus," by Dr. C. Ferrini.—Note on Virgil and his Italian imitator, Parini, by Prof. Cr. Fabris.—On Antonio Angeloni Barbiani and his literary productions, by E. B. Prina.—Analysis of the mineral waters of Acquarossa, Canton of Ticino, by Prof. G. Bertoni.—Malformations in the urinary ducts in Bright's disease, by Prof. C. Golgi.—Meteorological observations made at the Brera Observatory, Milan, during the month of March.

SOCIETIES AND ACADEMIES

London

Royal Society, May 1.—"Report to the Solar Physics Committee on a Comparison between Apparent Inequalities of Short Period in Sun-spot Areas and in Diurnal Temperature Ranges at Toronto and at Kew." By Balfour Stewart, M.A., LL.D., F.R.S., and William Lant Carpenter, B.A., B.Sc. Communicated to the Royal Society at the request of the Solar Physics Committee.

It has been known for some time that there is a close connection between the inequalities in the state of the sun's surface as denoted by sun-spot areas and those in terrestrial magnetism as denoted by the diurnal ranges of oscillation of the declination magnet; and moreover the observations of various meteorologists have induced us to suspect that there may likewise be a connection between solar inequalities and those in terrestrial meteorology.

This latter connection, however (assuming it to exist), is not so well established as the former, at least if we compare together inequalities of long period. It has been attempted to explain this by imagining that for long periods the state of the atmosphere as regards absorption may change in such a manner as to cloak or diminish the effects of solar variation by increasing absorption when the sun is strongest, and diminishing absorption when the sun is weakest.

On this account it seemed desirable to the authors to make a comparison of this kind between short-period inequalities, since for these the length of period could not so easily be deemed sufficient to produce a great alteration of the above nature in the state of the atmosphere.

The meteorological element selected for comparison with sun-spots was the diurnal range of atmospheric temperature, an element which presents in its variations a very strong analogy to diurnal declination-ranges.

There are two ways in which a comparison may be made between solar and terrestrial inequalities. We may take each

individual oscillation in sun-spot areas, and find the value of the terrestrial element corresponding in time to the maximum and the minimum of the solar wave. If we were to perform this operation for every individual solar inequality, and add together the results, we might probably find that the magnetic declination range was largest when there were most sun-spots. If, however, we were to make a similar comparison between sun-spot daily areas and diurnal temperature-ranges we might not obtain a decisive result. For at certain stations, such as Toronto, it is suspected (the verification or disproval of this suspicion being one of the objects of this paper) that there are two maxima and two minima of temperature-range for one of sun-spots. The effect of this might be that in such a comparison the temperature-range corresponding to a maximum of sun-spots might be equal in value to that corresponding to a minimum, or, in other words, we should get no apparent result, while, however, by some other process proofs of a real connection might be obtained. But if we can get evidences of apparent periodicity in sun-spot fluctuations when dealt with in a particular manner, we have at once a method which will afford us a definite means of comparison. And here, as Prof. Stokes has pointed out, it is not necessary for our present purpose to discuss the question whether these sun-spot inequalities have a *real* or only an *apparent* periodicity. All that is needful is to treat the terrestrial phenomena in a similar manner, or in a manner as nearly similar as the observations will allow, and then see whether they also exhibit periodicities (apparent or real) having virtually the same times as those of sun-spots, the phases of the two sets of phenomena being likewise allied to one another in a constant manner.

It is such a comparison that the authors have made, their method of analysis being one which enables them to detect the existence of unknown inequalities having apparent periodicity in a mass of observations. A description of this method has already been published in the *Proceedings of the Royal Society* for May 15, 1879. The comparison was made by this method between sun-spot observations extending from 1832 to 1867 inclusive, Toronto temperature-range observations extending from 1844 to 1879 inclusive, and Kew temperature-range observations extending from 1856 to 1879 exclusive. The following conclusions were obtained from this comparison:—

1. Sun-spot inequalities around twenty-four and twenty-six days, whether apparent or real, seem to have periods very nearly the same as those of terrestrial meteorological inequalities as exhibited by the daily temperature-ranges at Toronto and at Kew.

2. While the sun-spots and the Kew temperature-range inequalities present evidence of a single oscillation, the corresponding Toronto temperature-range inequalities present evidence of a double oscillation.

3. Setting the celestial and terrestrial members of each individual inequality, so as to start together from the same absolute time, it is found that the solar maximum occurs about eight or nine days after one of the Toronto maxima, and the Kew temperature-range maximum about seven days after the same Toronto maximum.

4. The proportional oscillation exhibited by the temperature-range inequalities is much less than the proportional oscillation exhibited by the corresponding solar inequalities.

Chemical Society, May 15.—Dr. Perkin, F.R.S., president, in the chair.—The following papers were read:—On refraction equivalents of organic compounds, by Dr. J. H. Gladstone. In this paper is given a series of tables embodying the results of observations made from time to time since 1870. In these tables the refraction equivalents for the line A for about 140 substances are given and compared with the refraction equivalents calculated from the following values of the respective elements:—Carbon (saturated) 5·0, carbon in C_nH_n 5·95, carbon double-linked 6·1, hydrogen 1·3, oxygen single bond 2·8, oxygen double bond 3·4, nitrogen 4·1, nitrogen in bases, NO_2, &c., 5·1, chlorine 9·9, bromine 15·3, iodine 24·5, sulphur single bond 14·1, sulphur double bonds 16·0.—On the estimation of silicon in iron and steel, by T. Turner. The author has compared the various methods of analysis, and concludes that the chlorine process suggested by Watts, with certain modifications, is applicable to all classes of iron, and is on the whole the best.—Note on the melting-points and their relation to the solubility of hydrated salts by Dr. W. A. Tilden.—Note on ferric sulphocyanate, by A. J. Shilton. The author finds that a large excess of potassium sulphocyanide or of boiling hydrochloric acid interferes with the well-known blood-red colour given by ferric salts and a sulphocyanide.—A memoir detailing some minor researches on the action of ferrrous sulphate on plant life, by Dr. Griffiths. The author finds that 0·15 per cent. of ferrous sulphate added to a solution of various salts aids, whilst 0·2 per cent. is fatal to, the development of mustard seeds and cabbage plants.

Physical Society, May 10.—The meeting was held in the chemical theatre of the Mason College, Birmingham. Members had previously visited some of the factories in the town, including Gillott's pen works.—Dr. Guthrie, president, took the chair at three p.m., when Prof. J. H. Poynting made a communication on an experiment illustrating the refraction of water-waves. The experiment was designed to illustrate by means of waves in water the refraction of waves when they pass from one medium to another in which their velocity is different. The apparatus consisted of a tank 2 feet 6 inches square, with a plate-glass bottom. Water is poured into the tank to a depth of say 5 to 6 mm. The lid of the tank consists of a calico screen, and is slightly tilted up. A limelight under the tank projects the wave on a screen. Plates of glass 3 or 4 mm. thick are placed in the tank, thus reducing the depth of water. If waves are sent across the tank they travel more slowly through the shallow water, and are seen to be refracted. When circular or lenticular plates are used, the refracted waves are seen to converge to a focus.—Mr. C. J. Woodward exhibited an oxy-hydrogen lantern suitable for lecture purposes.—Dr. Gladstone took the chair, and Prof. Guthrie, president, exhibited a sealed tube containing 46·6 of tri-ethylamine, and 53·4 of water. At temperatures between 0° C. and 18·3° C. the liquid forms a clear mixture. At 18·3° it becomes turbid, and at 26° C. almost perfect separation is effected. It was stated that all proportions of the two liquids containing about 15 per cent. and 50 per cent. of triethyl amine become turbid at the same temperature. A mixture containing 4 per cent. requires a temperature of 41° C. to produce turbidity, while one containing 90 per cent. is turbid at 6° C. A series of sealed glass bulbs containing the liquids in different proportions can be employed to indicate the fever temperature of the body if placed under the tongue. The author also showed the connection between such separation by heat and the separation between the same two bodies by cold, whereby in the latter case, according to the strength of the solution, either ice or subcryohydrate is separated, until the composition and temperature of the cryohydrate is reached (19·2 per cent.; −3·8° C). The peculiar white condensed vapour of the chloride of triethylammonium was exhibited. The white fume of this body so quickly aggregates into masses, that the shapes of the smoke-lines and curls are preserved. Dr. Gladstone agreed with the author in supposing that the separation of triethylamine and water was continuous in nature with the separation of ammonia from water by heat. Dr. Tilden exhibited a tube containing a cold, clear solution of amylic alcohol in water which became turbid on gently warming, and clear again on heating to about 60° C. He suggested that a similar remixing might take place with ethylamine and water. Prof. Silvanus P. Thompson recalled the experiments of Prof. Ramsay on the critical state described by Andrews, and the failure of a body beyond the critical condition to retain in solution the substances it held as a liquid. Mr. W. Lant Carpenter suggested the microscopic examination of the triethylamine and water mixture at its critical temperature.—Members then visited the College rooms.

Royal Microscopical Society, May 14.—Rev. W. H. Dallinger, F.R.S., president, in the chair.—A resolution was passed altering the by-laws so as to make ladies eligible as Fellows of the Society, but without the right of attending ordinary meetings.—Dr. Golding Bird exhibited a new freezing microtome of his construction, adapted for students and intermittent workers, and for use with ice and salt, or with ether.—Mr. Boecker showed an extensive series of Bacteria, Bacilli, and other Schizomycetes.—A very curious microscope of the date of 1772 was exhibited by Mr. Crisp, in which, with other peculiarities, three objectives were attached to a sliding plate at the end of the nosepiece in a way similar to that adopted in the modern Harley and other microscopes. Also two microscopes by Reichert of Vienna, one with a very simple form of Abbe condenser, and the other with a polarising prism attached to a swinging and rotating diaphragm.—The following apparatus and objects were also exhibited and discussed:—Frog plate made of glass, with serrated edges for the string; Griffiths' multiple eyepiece (an attempt to combine four eyepieces in one by fixing different eye-lenses in a rotating disk); Bradley's "mailing boxes" for sending one or several slides conveniently

by post; Dancer's objects found in flue-dust and coal-ash; Stokes' minnow-trough; B. W. Thomas's Foraminifera obtained by washing clay from the boulder drift in Minnesota, showing forms identical with some now found living in the Atlantic Ocean; some exceptionally well mounted slides of arranged Diatoms by R. Getschmann of Berlin; some curious Schizomycetes by Mr. Cheshire, and a rotalian from closed flint nodular cavity metamorphosed into chalcedony, by Dr. G. C. Wallich.—Dr. P. H. Carpenter gave an account of his views respecting the nervous system of the Crinoidea, and exhibited some preparations in illustration of them. He directed attention more particularly to the branches from the axial cords of the skeleton, which extend upwards into the ventral perisome at the sides of the ambulacra, both of the arms and of the disk.—The President, Mr. Glaisher, vice-president, and Mr. A. W. Bennett, a member of the Council, were appointed a deputation for the Society, to attend the annual meeting of the American Society of Microscopists at Rochester, N.Y., U.S.A., on August 19 next.

Royal Meteorological Society, May 21.—R. H. Scott, F.R.S., president, in the chair.—Capt. W. W. Hampton and C. D. F. Phillips, M.D., F.R.C.S., F.R.S.E., were elected Fellows of the Society.—The following papers were read:—Notes on the proceedings of the International Polar Conference held at Vienna, April 17 to 24, 1884, by R. H. Scott, F.R.S., president.—Meteorological observations on the Maloja Plateau, Upper Engadine, 6000 feet above the sea, by Dr. A. T. Wise. The Maloja Plateau is situated at the higher extremity of the Upper Engadine, and is protected from northerly, easterly, and southerly winds. The author gives some account of the meteorology of this plateau, and also the observations made during the four months from November 1883 to February 1884.—On some results of an examination of the barometric variations in Western India, by A. N. Pearson.—Illustrations of the mode of taking meteorological averages by the method of weighing paper diagrams, by R. Inwards, F.R.A.S.—Ten years' weather in the Midlands, by Rupert T. Smith.

EDINBURGH

Royal Society, May 5.—Mr. Robert Gray in the chair.—Dr. Sang gave a paper on the formulæ for computing logarithmic sines.—Mr. J. Murray communicated a paper, by Mr. J. T. Cunningham, on a new Trematode.—Mr. George Seton read a paper on the vital statistics of Scotland; and Prof. Turner gave a communication, by Mr. A. Wynter Blyth, on the results of experiments made by him on the chief disinfectants of commerce. His object in experimenting was to discover their efficiency in destroying the spores of *Anthrax bacillus*.

May 19.—Mr. Robert Gray, vice-president, in the chair.—Prof. Chrystal communicated a note, by M. Hermite, "Sur la Reduction des Intégrales Hyperelliptiques."—Prof. Schuster, at the request of the Council of the Society, gave an address on the discharge of electricity through gases. His address was illustrated by several beautiful experiments.

PARIS

Academy of Sciences, May 19.—M. Rolland, president, in the chair.—Note on a theorem of M. A. Lindstedt concerning the problem of the three bodies, by M. F. Tisserand.—On bromic substitutions, by MM. Berthelot and Werner.—Kinematic analysis of the action of walking in man (four illustrations), by M. Marey.—Note on the twenty-three first sheets of the map of Africa to the scale of 1 : 2,000,000, presented by Col. Perrier to the Academy, by M. F. Perrier. The map, which is mainly the work of Capt. de Lannoy, will consist altogether of sixty-two sheets, and is expected to be completed towards the end of 1887.—Pathological experiments on rabies, by M. Pasteur, assisted by MM. Chamberland and Roux.—Note on the attenuation of cultivated virus treated with compressed oxygen, by M. A. Chauveau.—Note on the transformation of conicine to propylpyridine; regeneration of conicine, by M. A. W. Hofmann.—Observations on the new planet 236 (discovered at Vienna, by M. J. Palisa, on April 26, 1884), made at the Paris Observatory (equatorial of the west tower), by M. G. Bigourdan.—Determination of the elements of rotation of the sun, by M. Spörer.—Properties of nine points of a left curve of the fourth order, of seven points of a left cubic, of eight associated points, by M. A. Petot.—On a linear equation of the third order analogous to Lamé's equation, by M. E. Goursat.—Remarks relative to the velocity of propagation of the wave produced in the Indian Ocean by the Krakatoa eruption, by M. THE ORIGIN OF THE CRYSTALLINE SCHISTS

Untersuchungen über die Entstehung der Altkrystallinischen Schiefergesteine mit besonderer Bezugnahme auf das Sächsische Granulitgebirge, &c.," von Dr. Johannes Lehmann. (Bonn: Hochgürtel, 1884.)

NO problem in modern geology stands out with such prominence as the origin of that remarkable group of rocks to which the name of the Crystalline Schists has been given, and to none in recent years has so large a share of the literature of the science been devoted. The question is attacked on all sides. By some observers its solution is sought in laborious investigations of the hilly and mountainous regions where these rocks hold their empire among the grander solitudes of nature. By others the question is studied in the quiet of their own libraries or laboratories with all the resources of modern chemistry and microscopy. Great progress has indeed been made in these various ways. Regarding certain aspects of the problem a general agreement has been arrived at; but there are others as to which the difficulties remain as persistently obstructive as ever.

One of the most important contributions to the study of this fascinating subject has just appeared in the form of a handsome quarto volume, with a large atlas of plates, by Dr. J. Lehmann. This author has enjoyed exceptional opportunities of qualifying himself for the task he has now undertaken. For nine years, as a member of the Geological Survey of Saxony, he was engaged in the investigation of the classical granulite-region of that kingdom, of which he surveyed the southern and rather larger half, while his colleague, Mr. E. Dathe, investigated the northern part. The maps of this Survey are accompanied with explanatory pamphlets, among which Dr. Lehmann's detailed local observations have already been published. But it was desirable to present a generalised description of the whole region and to discuss the bearings of the observations upon theoretical questions. He originally proposed to undertake this task in association with Mr. Dathe; but his transference to Bonn as Privat-docent in Mineralogy and Geology, and the removal of his friend to the Prussian Geological Survey, having prevented the intended cooperation of the two observers, Dr. Lehmann has himself worked up the mass of materials collected during his long course of work in the field. To enlarge the scope of his inquiries and obtain additional data for comparison he has recently extended his investigations into the Erzgebirge, Fichtelgebirge, and the mountains of the Bavarian and Bohemian frontier. And he now offers what we may hope is only a first instalment of his results.

Naumann, whose early account will always be cited as a model of careful observation and accurate description, regarded the granulite of Saxony as an eruptive rock—an opinion in which he has still modern followers, including our author himself. He recognised a fact which seems in more recent times to have been lost sight of, that a gradation can be traced from the more highly crystalline condition of the granulite centre, through successive zones of mica-schist, and other schists, into the older sedimentary rocks of the surrounding districts. These schistose rocks have in more recent times been classed as "Archæan," and as such they appear on the maps of the Saxon Geological Survey, Dr. Lehmann having himself accepted this view in his earlier published descriptions. But more extended study of the subject has induced him to abandon the idea of the existence of any Archæan nucleus and to return to a modification of the original conception of Naumann. How he has been led to this conclusion it is the object of his volume and atlas to show.

Under the deep cover of post-Tertiary deposits, the granulite tract of Saxony forms a central ellipse round which zones of various schistose rocks are grouped, that pass outwards into the normal clay-slates of that part of Germany. These slates on the south-eastern margin are unconformably overlaid by Silurian and Carboniferous rocks. On the north-west side a conformable sequence is traceable from the schists and slates upwards into Cambrian and Lower Silurian rocks, which are precisely like those of the adjacent countries. Instead of being Archæan masses, Dr. Lehmann concludes that the whole of the crystalline schists within the granulite area are metamorphosed Palæozoic sediments. They may be originally of Silurian or Cambrian age, and their metamorphism probably took place during the crumpling and upheaval of the area, that is, later than the Devonian and older than the Carboniferous period.

Towards the establishment of this conclusion the author brings forward a vast mass of detail, which he skifully arranges so that its bearings upon theoretical questions may be clearly seen. At the same time he endeavours to separate rigidly what is demonstrable fact from what is mere inference, and in this lies one of the most valuable features of his memoir. He has collected such a body of evidence as will give a new impetus to the study of metamorphism, while at the same time it provides abundant new and suggestive material for the prosecution of this study. He justly cites the Saxon granulite area as a classic example of the occurrence and origin of metamorphic schists where a complete gradation can be followed from unaltered or little altered sediments into wholly crystalline foliated masses. In this progressive intensity of metamorphism the most notable fact is the corresponding advance in the development of mica. Over and above all local diversities of mineral character, there is a constant augmentation in the quantity and size of the mica-folia. At the same time the muscovite, which is alone present in the outer parts of the area, is replaced further inwards by biotite. Nor is this change confined to the peripheral schists; it extends into the granulite of the centre. Such a rearrangement of the mineral constituents of the rocks cannot be explained by any hypothesis of an eruptive granitic mass. Like so many other concurrent facts, it points to the effects of the molecular movements of the original rocks, sedimentary or other, under the strain to which they were subjected during the process of crumpling and upheaval. Where these movements have been greatest, there the accompanying metamorphism has been most intense, and, as one prominent indication of this change, there is the

most abundant development of biotite. Every student of the crystalline schists can furnish parallel examples to those cited by Dr. Lehmann where, on the zigzag puckerings that form so striking a feature among these rocks, a copious growth of biotite or some other mica has taken place.

Among the metamorphosed rocks of the Saxon region some of the most instructive are bands of conglomerate interstratified among the schists. The sedimentary origin of these zones is of course unquestionable, and so obvious that the alteration to which they have been exposed furnishes a kind of sample of the initial stages of change which are so often lost where the clastic materials are of a less prominent and obdurate character. The pebbles of granite, quartz, &c., have been deformed and more or less altered, so that sometimes they seem to shade off into the surrounding matrix. The latter has become a crystalline micaceous mass by which the pebbles are wrapped round. These conglomerate bands have thus been converted into half-crystalline gneiss-like schists.

A specially important part of the memoir deals with Gabbros and Amphibolites. These rocks, as members of the series of crystalline schists, have long been a puzzle to those who have studied them in the field. That they are metamorphic rocks, and not rocks of original chemical precipitation, has been inferred from their association with masses whose original sedimentary origin admits of no doubt. But even those who have held this view have hesitated as to the nature of the original masses out of which they have come. Many years ago Jukes suggested that hornblende-rocks and hornblende-schists might represent ancient lavas and tuffs interstratified with the sediments which are now schists and quartzites. And it seems probable that this opinion is essentially correct. Dr. Lehmann goes into great detail regarding the structure of the diallage and hornblendic rocks of the granulite tract. His study of them leads him to conclude that the gabbro is an eruptive rock, younger than the granulite but older than the granite, which has been involved in the general metamorphism and has consequently assumed schistose modifications. "I know no rock," he adds, "which illustrates so well the effect of mechanical pressure upon a solid rock as the gabbro of the Saxon granulite tract. While other rocks leave us in doubt as to their original condition, the gabbro supplies us with every stage from the beginning to the end of the metamorphism." These conclusions possess at present a special interest in relation to the crystalline schists of this country. The Geological Survey, in the course of an investigation of the schists of the north of Scotland, has recently come independently to similar deductions with regard to the diorites and amphibolites of Aberdeenshire and Banffshire. Among the schists of that region there occur extensive masses of diorite. This rock presents sometimes the typical composition and structure of a diorite, and under the microscope appears as one of the most beautiful examples of a thoroughly crystalline granitoid mass. It behaves in the field as an eruptive rock, which has risen generally parallel with, but also transgressive across, the bedding of the contiguous schists. It is obviously from these characters a mass that has been intruded into the clay-slates, knotted-schists, and other schists of the district. Being traversed by veins and bosses of granite, its protrusion was obviously earlier than that of some at least o[f] granite. Further examination of it, however, shows in many places it presents a remarkable parallelism i[n] arrangement of its crystalline constituents. Somet[imes] this is shown by the orientation of the feldspars in definite direction. In other places the feldspar and h[orn]blende are drawn out into more or less distinct ba[nds]. Further stages of change reveal the feldspar segregated into an almost pure labradorite rock, while the hornblende appears as a felted mass of hornblende-schist. Some of these schistose aggregates are of exquisite beauty. Over wide tracts biotite has been abundantly developed in the diorite, and sometimes also numerous and large kernels of garnet. It is observable that the direction of the foliation of the diorite coincides with that of the surrounding schists. There seems no reason to doubt that, as these Scottish schists are metamorphosed Lower Silurian sediments, the diorites and amphibolite-schists represent Palæozoic eruptive rocks that have participated in the general metamorphism. Dr. Lehmann recognises, in the Mica-schist and Phyllite groups, hornblende-schists which he thinks may have been embedded masses of diabase that have been more or less altered.

His general conclusions are thus summed up:—"I cannot regard the metamorphic schists (mica-schists, gneisses, &c.) as 'Archæan' formations. It does not appear to me to be established that genuine gneisses anywhere came out of pre-Cambrian sediments. The production of such rocks as mica-schist, &c., belongs to the time of mountain-upheaval, and in actual fact has involved formations of far younger age than the Cambrian. In the Saxon granulite region it is later than the Devonian period." He draws a distinction between what he considers to be "true gneisses" and other rocks to which the general name of gneiss has been applied. He restricts the appellation to the foliated forms of granite. This foliated or true gneissic structure he believes to be more or less due to metamorphism by stretching, seldom wholly original, so that many gneisses may be called metamorphic; only, the original rock was not a sediment but a mass that consolidated from fusion (Erstarrungsgestein). We fear that a theoretical distinction of this kind will involve all kinds of practical difficulties in its general application.

Reference must be made to the atlas that accompanies the memoir. It contains 28 plates, on which are placed no fewer than 159 photographs of thin sections of the rocks described in the text. Unlike the usual illustrations of this kind, these photographs represent the objects of the natural size, or less, or at most only slightly magnified. They are not microscopic studies, but show the actual structure of the rocks as seen by the naked eye or with a weak lens. It is impossible to speak too highly of the success with which they have been produced. With their aid we are rendered in some measure independent of the actual specimens, and can follow with pleasure and satisfaction the detailed descriptions of the author. No such wealth of accurate illustrations has yet been furnished for the study of this important series of rocks. Dr. Lehmann, however, is, we hope, only on the threshold of his inquiries. A vast domain lies before him where the problems are many and the qualified observers are but few. He has done excellent service by presenting in this compendious form such

an array of facts as a trained geologist can gather in the field, and by boldly announcing the conclusions to which the study of these facts has led him. But much more may be made of them than he has yet given us. And we trust he may be encouraged to continue the investigation he has so well begun. ARCH. GEIKIE

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

The Marine Biological Association

WILL you allow me space to ask all naturalists and lovers of science who intend to become members of the above Association to send their names and subscriptions *without delay* to Mr. Frank Crisp, 6, Old Jewry, London, E.C. The subscription is one guinea annually, or fifteen guineas for life membership. It is highly desirable that intending members should at once enrol themselves, since the first meeting of the Association for the election of officers and council for the year 1884-85, and for the ratification of by-laws, will be held in London at the end of this month, when Prof. Huxley will be nominated as President. Donations, whether large or small, are earnestly solicited. Those who are interested in the natural history of marine plants and animals, and who foresee the immense help to this study which a well-equipped laboratory will afford, are begged not only to give some pecuniary aid to the present enterprise, but to constitute themselves agents of the Association and to do their best to persuade others to contribute to the fund required for building the first biological laboratory on the English coast. It is only by hearty and earnest support of this kind that our object can be realised.

I may add that several naturalists have contributed each 100*l.* to the Association, others 25*l.*, and others less, according to their means and their sympathy with our object. Of the 10,000*l.* required, we have not yet obtained half.

E. RAY LANKESTER,
Secretary (*ad interim*)

11, Wellington Mansions, North Bank, N.W.

The Equatorial Coudé of the Paris Observatory

IN continuation of my first letter I now proceed to answer M. Lœwy's second letter, as published in your issue of May 15 (p. 52).

M. Lœwy has not, as I said in that former letter, raised a single objection which had not already been anticipated and discussed with the exception of one which I shall treat of further on. The several points in this letter I shall dispose of very shortly.

1. As to the dialyte construction, I have to reply that that particular method of achromatising the objective is not an *essential* feature of this instrument. Whether it be adopted or not is in fact much a question of *cost*. If the purchaser desires to get the largest possible aperture at least expense, then I would make it a dialyte, for, notwithstanding all M. Lœwy says, good work can be and has been done with dialytes. If, however, the most perfect instrument is desired, I would dispense with the dialyte construction, and achromatise the object-glass in the ordinary way, which is quite as applicable to my construction of equatorial as is the dialyte. If I mistake not, the celebrated observer M. Dembowski observed for many years with a dialyte, and spoke highly of it; he says: "*L'achromatisme est excellent.*" Again, the present director of the observatory, for whom the first of these instruments is to be made, has worked already with dialytes, and he would not be likely to recommend this construction if his experience agreed with M. Lœwy's. I desire to notice just one further point in this part of M. Lœwy's letter, as it is another example of how his own words (unintentionally, no doubt) confirm my statements. He says (speaking of the limited field of view of dialytes): "But, in order to turn the difficulty, he" (Mr. G.) "suggests that since the field of view becomes smaller as the instrument becomes larger, we may content ourselves with observing at a central point." I never said this; my words were: "The definition at the edge of the field, however, is not so good as in the ordinary form, but this would not be of so much consequence in large instruments, as the field in such cases is never of great extent." And M. Lœwy himself corroborates this for me when he says: "For the observation of comets I have such an eyepiece, which magnifies fifty times, and has a field of view such that I can observe a degree (*i.e.* with the 12" equatorial *coudé*); for a telescope of 27 inches we might have such an eyepiece with a field of 24 minutes." Thus I have a distinct corroboration from M. Lœwy of what I said above.

2. Writing on the matter of stability, M. Lœwy curiously mixes up stability and accuracy of movement. Now while I claim that I can and will obtain greater stability in my form than exists in M. Lœwy's, I do not claim accuracy of movement, but on this point I propose to say very little at present for several reasons. In the first place, it would hardly be possible to discuss this and put it in an intelligible form to your readers without a careful drawing; secondly, the well-known stability of the instruments which have emanated from my workshops are quite sufficient guarantee that this point is not one likely to be neglected in any of my work; and thirdly, I find it utterly impossible to understand the sentences of M. Lœwy's paper bearing on this point, and if I, though familiar with the proposed construction, fail to understand them, I am hopeless of serving any useful purpose by discussing them in your columns, particularly as few of your readers have ever seen the design of the instrument referred to. M. Lœwy talks of "all movements of transmission being broken at right angles." I do not know what he means, but he omits to tell your readers that, according to my design, in the larger sizes I propose that all movements be effected by two hydraulic cylinders the valves of which are within reach of the observer while sitting in his chair; so that, without more physical exertion than is necessary to open a water-tap, he has full command of all the movements of the great instrument, a pair of vertical scales on the walls of his study giving the approximate position of instrument in Æ and declination, an arrangement eminently calculated to reduce the work of the observer.

3. Lastly, as to its want of universality. This is distinctly stated in my paper as a disadvantage of my form; but when M. Lœwy asserts that "it is based on a principle which no astronomer can admit, viz. that it is superfluous to observe the greater part of the northern heavens," it is evident that M. Lœwy has here gone too far, since that portion of the heavens within 20° of the Pole is only about 6 per cent. of the northern hemisphere. Ask any practical astronomer possessing a moderate-sized equatorial how many hours out of the total number of hours which he has worked in the year has his instrument been pointed to objects within 20° of the Pole, and, with the exception of a few who apply themselves to special work, the great majority will give a reply which will show how very little will be lost by the fact that this instrument cannot command that portion of the heavens. I have myself put this question to many, and with the result above mentioned. On this point I cannot do better perhaps than give an extract from a letter I have just received from the director of one of our public observatories:—"Instruments of large aperture are rarely if ever used for observations where extreme accuracy of measurements is required, such as annual parallax, nor for searching for nor observing comets, except to search along a known track for an expected periodical comet. This your instrument could do well. There is hardly an instrument in existence which is equally well adapted to all kinds of observations. The circumpolar zone of about 20° may be explored by other instruments, but for almost every kind of *systematic* work the remainder of the visible heavens will give plenty to do." The foregoing would be a sufficient answer to a question which M. Lœwy has put directly to me.

He says:—"Permit me to ask Mr. Grubb how he is going to study that part of the heavens which lies between 20° from the zenith and the Pole."

To any one who has seen my paper it will be evident that this point, which in M. Lœwy's letter is put forward as a discovery of his own, was already fully dealt with by me. I said: "The instrument commands the heavens from east to west and from south horizon to about 20° beyond zenith" And again: "As regards this instrument (equatorial *coudé*) I would observe that it possibly possesses an advantage over my form in being absolutely universal."

No doubt universality unaccompanied by such disadvantages as the equatorial *coudé* possesses is very much to be desired, but I do not yet see how it is to be obtained. With respect to the solitary original objection that M. Lœwy has raised, viz. that the light reflected by the mirror varies with the different angles of inclination, and therefore renders the instrument unfit for photometric researches, I confess this objection did not occur to me before, and I am inclined to think M. Lœwy is right, and that my instrument will not be well adapted for photometric researches, but I ask: Is the equatorial *coudé* any better? On consideration it will be evident to your scientific readers that the light after the first reflection is elliptically polarised, and if so the quantity reflected by the second mirror is variable at the various angles of declination; consequently photometric observations made with the equatorial *coudé* cannot be relied upon.

In attempting to prove his case M. Lœwy gives in his first letter a considerable number of numerical details, and no doubt most of your readers have taken these figures as correct. I will ask them, however, to verify for themselves a few of them, and the result will, I think, show how very loosely M. Lœwy has put these data together. For instance, he mentions the weight of a 40-inch mirror, whose thickness is just one-sixth of the diameter, to be 380 kilos., and he calculates (see further down) that a mirror of 38 inches diameter and proportional thickness would weigh 280 kilos.—100 kilos. less. Now, if the thickness be proportional, the weight should be as the cube of the diameter. If your readers will try this themselves, they will find that M. Lœwy has in this case exaggerated the difference to the amount of about 100 per cent.

I find I omitted to notice just one point in Mr. Lœwy's first letter. He says:—"If Mr. Grubb had looked at the drawing which I published in the *Journal de Physique* of last year, he would have seen that it is almost identical with that which he has communicated to the Royal Dublin Society, so far as the general arrangements for sheltering the observer and instrument are concerned."

Permit me to inform M. Lœwy that this would hardly have been a novelty to me last year, inasmuch as I had such arrangements not only on paper but in actual work for some years back, and a description of the same was published in the Royal Dublin Society's *Proceedings*, April 1879.

Your readers will see from the foregoing that M. Lœwy's whole letter is based on a series of misconceptions of statements in my paper in the *Transactions* of the Royal Dublin Society.

Some of the mistakes that M. Lœwy has fallen into were perhaps due to the fact that the plate issued with the Royal Dublin Society's *Transactions* was merely a diagram without details, introduced to illustrate the principle of the mounting. He assumes that details not figured in the diagram are not to be provided, in spite of the fact that in the text of my paper I discussed several of them.

M. Lœwy occupies nearly half a column of NATURE in speaking of the labour involved in working this instrument, because no tube is shown in the diagram connecting the equatorial part with the ocular; all this trouble would have been saved if he had read my paper a little more carefully, for then he would have found that not only did I say, "In most cases it would be desirable to have a connecting tube," but I even discuss the best form of tube for the purpose. There are some special cases in which a tube would not be actually necessary.

It appears to me that M. Lœwy is very unnecessarily disturbed in his mind by the advent of my instrument. No doubt the equatorial *coudé* and my siderostatic telescope have each their own sphere of work, and there may be room for both. An observatory having at its back a generous individual who (as was stated at a late meeting of the Royal Astronomical Society), has already expended a quarter of a million on astronomical observatories and is willing to spend more, can afford a large instrument perhaps on M. Lœwy's plan; but as all observatories are not equally fortunate, there may occasionally be one found which will be glad to get equally great optical power at one-third the cost.

I barely alluded in my last letter to this question of cost. On this point it may be desirable to supplement what I have said in my former letter, bearing in mind that the cost of the instrument will, as I have above stated, depend somewhat on whether or not the objective is achromatised on the ordinary principle or that of the dialyte.

In order to put the matter of cost in the clearest light, let us consider the four forms which we have at present to select from, viz. the ordinary equatorial, M. Lœwy's equatorial *coudé*, my siderostatic telescope with objective achromatised in the ordinary way, and the same instrument with objective achromatised on the dialyte principle.

Let us consider first what apertures we can obtain in the several forms for a given sum; assuming M. Lœwy's figures for the equatorial *coudé*. For 1760*l.* can be obtained—

(*a*) Equatorial *coudé* of 12-inch aperture.

(*b*) Ordinary equatorial of 12-inch aperture, including its dome and observatory.

(*c*) Siderostatic telescope with objective achromatised in the ordinary way of 18 inches aperture.

(*d*) Siderostatic telescope with objective achromatised on the dialyte principle of 24 inches aperture.

It would be for the astronomer to say whether the double aperture of the objective would not more than counterbalance the disadvantages of want of absolute universality.

Let us, secondly, consider for what prices the *same* aperture could be obtained in the various forms:—

(*a*) Equatorial *coudé* 12" aperture	£1760
(*b*) Ordinary equatorial of 12" aperture, including dome and observatory	1760
(*c*) Siderostatic telescope of 12" aperture with objective achromatised in the ordinary way ...	1000
(*d*) Siderostatic telescope of 12" aperture, with objective achromatised on the dialyte principle	500

The difference between cost of equatorial *coudé* and siderostatic dialyte (about 1200*l.* for this size) will probably be considered by the purchaser rather too large a sum to pay for the possibility of examining the 6 per cent. of the northern hemisphere which is beyond the reach of my siderostatic telescope, particularly when it is borne in mind that that portion is the least important part of the heavens.

M. Lœwy does not say whether the 1760*l.* includes cost of observing hut. If not, the comparison is still more striking, for, although the equatorial *coudé* requires a special building, my siderostatic telescope does not. HOWARD GRUBB

Dublin, May 27

The Earthquake

CHANCE brought me to Colchester about a week after the earthquake, and since then I have been amusing myself mapping the effects of it, and hope to read a paper on the subject at the meeting of the Royal Geological Society, Ireland, next month. In the meantime I would like to draw attention to a few of the general facts that seem not to be recorded.

The area of structural damage lies at and southward of Colchester, principally to the west of the Colne estuary, and in it there are five smaller areas in which are found the greatest damage. These areas occur in the following order:—Wivenhoe, Peldon, Abberton and Langenhoe, Colchester, and West Mersea; each of these have two or more well-marked margins; where these margins can be easily studied, there are found to be lines of breaks, and alongside one, or in places two of them, the greatest destruction occurred, while at the other side of such lines the damage is a bagatelle in comparison.

Thus at Wivenhoe, where there was the greatest damage done, the shock came from the north-east; but when it reached the break of the Colne River valley, it seems to have recoiled as if from a percussion blow. Westward of the estuary of the Colne the damage at Rowhedge was slight when compared with that at Wivenhoe, while at Hornwood it was still slighter, although the last is only divided from Wivenhoe and Rowhedge by the valleys of the Colne and Roman Rivers.

At Peldon, where the shock appears to have been nearly as bad as at Wivenhoe, the damaged area is very well defined, being bounded northward and southward by stream valleys. The shock seems to have travelled southward and to have recoiled from the southern boundary, causing excessive damage alongside it. Here also the shock appears to have had a rotary motion, which possibly may be due to the recoil against the southern boundary.

In the Abberton and Langenhoe area the shocks seem also to have had a rotary motion, the main direction seems to have been from the south-east; here the greatest damage occurs at the western boundary.

At Colchester the shock was going north, while at West Mersea it went south. In both of these places the boundaries of the areas are in part obscure. In the first, however, we can trace the tract of maximum damage from Head Gate along the south Roman wall and eastward to Colne valley, east of which very

little damage was done. Thus everywhere except at West Mersea there are one or more lines, at one side of which there was excessive damage not to be found at the other side.

In the area of excessive damage, according to Mr. Dalton's map, the geological formations are *Alluvium*, *Glacial Drift*, and *London Clay*. On the first we find damage done to houses near Eastbridge, Colchester, and at Wivenhoe, although elsewhere they escaped. In the north portion of Wivenhoe and the north portions of Colchester, structures on the Glacial Drift were injured, but elsewhere the damage nearly invariably is confined to tracts and small exposures of the London Clay. This is very conspicuous in places—at Colchester there is a narrow outcrop of London Clay which widens eastward near the Colne, and on this narrow tract the greatest damage was done; similarly at Wivenhoe the excessive damage is along the outcrop of the London Clay. At Fingrinhoe and Frenchman's Lane the damage margins an outlying tract of Glacial Drift, while very good examples can be seen between Colchester and Ardleigh, the structures on narrow tongues of the clay being injured, while those on the intervening tracts of gravel have escaped, except in one instance.

Victoria Road, Colchester J. HENRY KINAHAN

ONE of the most curious effects of the earthquake in the Peldon district is the evidence of a decided *twist* or apparent rotation of the shock evident in many cases upon standing buildings. Is is very apparent in the cracks throughout Dr. Green's house, which take a complete screw round some of the rooms and the staircase. It is also evident in the twist of the tapering mill chimney shaft where the upper 20 feet (still standing) is screwed round at the fracture upon the lower part about one inch. The same is apparent in a chimney at the "Peldon Rose" Inn, the screwing in this instance being about two inches. As such twists as are evident could not exist within the areas of separate single buildings, it appears to me that they must have been the resultants of the effects of two separate shocks, the first about north to south, and the second immediately following about east to west. That there were two shocks appears to be the general impression of the inhabitants of whom I made inquiry. Another matter of interest is the very peculiar fracture of the eastern side of Dr. Green's house. This fracture leaves the lower northern corner of the wall, and passes diagonally across the house to the upper southern corner. The crack is open about one inch through solid modern brickwork. In this case the line of fracture does not follow a line of weakness in the wall, but cuts directly through the thick chimney breasts, and equally across a window opening, as though there was present no difference in resistance. The angle of fracture is about 47° to the horizon, and it appears to me that this must have been the direction of the first or greater shock in this district, which was therefore more one of upheaval than of horizontal motion. This is also confirmed upon inquiry, as I find many persons in the district felt distinctly the motion of upheaval, but no one who was standing at the time is known to have been thrown down.

W. F. STANLEY

DARWIN relates that the earthquake of February 20, 1835, which overthrew Concepcion, although it was severely felt in Chiloe, yet on the neighbouring Cordillera (near Mellipulli) it was not felt at all. "Some men who had been employed in the mountains splitting fir planks, when they returned in the evening to Calbuco and were told of the shock, said that 'about the time mentioned they recollected that they had not been able to strike fair with the axe, and that they had spoilt a board or two by cutting too deep.' This probably is not so fanciful as it appears; at least it shows that if there was any motion it was of an exceedingly gentle kind" (*Trans. Geol. Soc.*, vol. v. p. 605).

A parallel case occurred during the late earthquake in Essex. Some men hoeing wheat at Frating, about seven miles northeast of the focus of the shock, did not perceive the shock, but felt as if they could not get their hoes to the ground.

May 30 O. FISHER

Jupiter

THIS planet is now so unfavourably placed that very few further opportunities will occur of observing the chief features during the present apparition. It is, however, important that the red spot and equatorial white spot should be followed as long as practicable, and I give a list of the times when they will be situated on or near the central meridian:—

	Red spot h.		White spot h.
June 5	8·8	June 5	9·1
7	10·4	7	10·3
10	7·9	12	8·3
12	9·5	14	9·5
17	8·7	21	8·8
22	7·8	28	8·1

The two spots will come to the same longitude on June 7, but at the time of their transit Jupiter will be too low to admit of satisfactory observation.

Erratum.—The dark satellite transit which I observed on May 18 (NATURE, May 22, p. 77) referred to the *fourth* satellite and not to the first as described. The three dark spots seen were really the shadows of the first and second satellite and the fourth satellite itself. The first satellite was also projected on the disk of Jupiter at the time of the observation, but it was not seen under the form of a dark spot. The error in the original description arose from a mistake in the identification of the satellites and their shadows, four of which were on the planet at the same time.

W. F. DENNING

Bristol, June 1

Animal Intelligence

THE instances of intelligence which I am about to relate, to the credit of a cockatoo, were described to me by the owner, a lady, in whose presence they were displayed, as well as in that of several other witnesses, one of whom (her husband) was also present on two occasions when I heard the accounts.

The bird is fond of white lump-sugar, and ordinarily drops it into his saucer of tea or other drink to soften it. On one occasion when he was thought to be thirsty, a glass of water was offered him, which appears to have been of the goblet kind, about 6 inches high, with a foot and stem, and holding, it would seem, something more than a large wine-glass and less than a small tumbler. Shortly after, the bird received a piece of sugar, and, as usual, dropped it into the water. But now, alas! the depth of liquid was too great for him to recover the saturated lump; and unfortunately, not having myself witnessed the occurrence, I am unable to describe the indications of mental effort which doubtless preceded the attempt to solve the problem of extracting the lump of sugar before it should disappear. I was told that the like difficulty recurred next day, and, whether on account of the practical failure of the first attempt, or in consequence of a fresh inspiration at the moment, a different *and entirely successful* plan was then adopted. It is no doubt to be regretted that the experiment was not followed up, but the reason will shortly be apparent. Now, as to the first attempt. There was no endeavour to upset the glass; it was too high for the claw to be used, and too deep for the beak to be plunged in. To *drink* all the water would indeed have been, as remarked by the narrator, "an heroic remedy." What "Koko" *did* do was to *bale* the water out with his scoop-like lower mandible. Here again I find myself unable to describe the action more exactly, but it must have been in the highest degree interesting to watch the operation, with its increasing difficulty, and constantly diminishing prize at the bottom. Finally we may suppose that the sugar having disappeared the last portions were at least partly enjoyed. Still the result was to some extent evidently a disappointment; for on the next occasion "Koko," without the least hesitation, put in practice a device which we may fairly suppose he had thought out meanwhile. He began forthwith to drop in lumps of sugar one after another until the last was level with the surface, when he recovered that one and left the rest to their natural fate, while he peacefully enjoyed the fruits of his invention.

I have unfortunately too slight an acquaintance with the ways of these birds to know certainly whether this is above the average of their intelligent acts and as such worthy of space in your columns. For the same reason I hesitate to give, at second hand, other indications which, however interesting to me, might prove less so to others. I will only add that it is so distressing to see so nice a creature almost naked, through its inveterate propensity to pluck out every feather within reach, that I should be glad to hear of any possible remedy.

J. HERSCHEL

23, Suffolk Street, Pall Mall East, S.W.

P.S.—At the suggestion of a gentleman whose name is well

[The following is M. d'Abbadie's letter:—]

My Dear Sir,—I have met few people who can pen a narrative quite accurately as you have done. Were I writing history, I should add that "Koko" (a *Cacatua moluccensis*) seems to hail with satisfaction the appearance of a coffee-tray. As soon as it is laid on the table he lifts by its central knob the sugar bowl's cover, picks up a lump of sugar, and drops it in an empty cup, on which he taps with his beak to intimate that he is thirsty, for dry sweets are not to his taste.

This bird is the wonder and plague of my life. One day curiosity (?) impelled him to pull into shreds my only kaleidoscope. He got for his industry a few touches of a whip, which he tore to pieces twenty-four hours later, showing apparently that memory is one of his gifts. He has a knack of tearing my pens and papers, sometimes with good reason. As, however, I arrogate those privileges to myself, "Koko" is excluded from my study. Its door, partly glazed, has a pad to prevent draughts, and, before I added a bolt, was closed only by a knob two centimetres thick. Climbing along the pad eighty centimetres above the floor, he looked slily with one eye through the glass, and if the coast was clear he then proceeded to business by turning the knob with his powerful beak and then pulling it, while one claw pushed against the doorpost, the other holding on to the pad. Another door has a lock, and servants thought to exclude the intruder by turning the key, but "Koko" soon learnt to turn it back before applying his energies to the knob. Having thus put the door ajar, he descends cautiously with beak and claws along the pad, opens the door by a push or pull of his beak, as the case may be, and, stopping on the threshold, exclaims modestly, "Koko!" like a Wolseley or a Graham announcing his recent victory.

I say *modestly*, for this bird assumes often a haughty tone when uttering what we call his public speech. It is a rambling gabble, and, like the sayings of a French orator who shall be nameless, it is wholly unintelligible. However, its varying tones are splendid. Those of indignation and command prevail, but in the course of seeming argument "Koko" expresses also and most forcibly concession, interrogation, pity, disdain, ridicule, contradiction, and even logical inference. Without having read the Roman author who advises orators to take hold of their beards when pausing to reflect, "Koko" halts now and then his wordy torrent to seize his chin with his claw, as if pondering on the best line of action. Other appropriate gestures add to the seeming reality of his discourse. I have seen him stand suddenly on one leg, double up the other claw like a fist, and deal a blow on the air as if to knock down an enemy. In spite of their wide sleeves, our barristers might well envy the fulness of gesture imparted by his wings. He raises them expanded over his head, then throws them down impetuously before himself with a seemingly clenching argument. I have heard that Burke used his arms in the same way when beginning his outbursts of eloquence.

The wisdom of nations has sometimes found it necessary to put even statesmen in durance vile, and "Koko" has not escaped the lot of his betters. As, however, he contrived to unfasten several kinds of common spring padlocks, and even one which requires, like my door, three simultaneous manœuvres, my astronomical artist boasted of making one which would puzzle even a Christian. Our bird was chained with this ingenious invention, and immediately busied himself for about two hours pressing on every side the brazen problem. It seemed to cause a heavy expense of thought for his slender brains. On the following day he opened this new-fangled padlock, but with evident difficulty. Finally, having mastered it the third morning, he then freed himself with the greatest ease. Withal he cannot ged rid of a padlock that requires a key, nor has he yet pushed back a loose bolt on the very door where he overcomes a fastening apparently more complicated. May we infer that bird reason differs from human reason?

sideways, like the players, and took good care to laugh loudly at each pretended stumble.

The foregoing facts, where a bird's reasoning powers seem to rival those of men, suggest two questions: (1) Where is the boundary between them? and (2) whether intelligence depends, as is often supposed, merely on size of brain? Unable to answer these queries, I remain very truly yours,

Antoine d'Abbadie,
de l'Institut de France

Paris, May 20, 1884

METEOROLOGY IN VICTORIA

The monthly and other publications on meteorology and terrestrial magnetism issued by the Melbourne Observatory continue to be regularly received by us, the last *Monthly Record* being for December 1883. Since we reviewed these *Records* (Nature, vol. xiv. p. 153) we have observed with much interest the steady, and latterly the rapid, extension of climatological stations over the colony. During the ten years ending December 1883, while the number of fully equipped stations has remained nearly the same, stations at which temperature is observed have increased from 10 to 27, and stations for rain observations from 34 to 170. These 170 stations are conveniently classed into coast, watershed, and river-basin groups, and the individual gauges of each group are further arranged in the tabular returns in the order of their heights, which rise to about 4000 feet. The *Records* conclude with a detailed report for all the stations of thunderstorms, hail, snow, frost, gales, hot winds, auroras, earthquakes, &c., observed during the month.

While isobars can be drawn with tolerable correctness from the observations of a small number of stations, and isothermals from the returns of a few more, but still a comparatively small number of stations, it cannot be too strongly insisted on that a very large number of rain-gauges are required to give even a tolerable approximation to the actual rainfall of a country for a definite period, say, a week or a month, which may not seriously mislead those interested in the rise and fall of prices of agricultural and other products that depend on the weather. The meteorological authorities of South Australia and New South Wales are, equally with Mr. Ellery, so fully alive to the paramount importance of an adequate observation of the rainfall, that after a few years' continued vigorous effort this large portion of Australia will take rank, in respect of its rainfall, as one of the best observed regions of the globe.

At Melbourne the wind is observed and the results are discussed with admirable fulness. In summer the prevailing winds are southerly, and in winter northerly. The strongest winds are north and north-west, and the lightest east and south-east, the south-easterly winds in some seasons blowing with only about a third of the velocity of the north-westerly winds. The diurnal velocity of the wind falls to the minimum from about midnight to 4 a.m., and rises to the maximum from about 10 a.m. to 4 p.m. As regards season, the absolute maximum occurs at noon in winter, but in summer two hours later. Another important feature in the diurnal velocity of the wind is that from April to August the daily maximum is only a half more than the minimum velocity, whereas from October to February it is more than double. In other words, the maximum velocity rises to a greater extent above the daily mean during the period of the year when the temperature

is rising from winter to summer than when it is falling from summer to winter, agreeing in this respect with what has been observed in similar regions.

The *Monthly Records* give, in addition to the month's results, the averages of that month for each station based on previous years' observations. In the review referred to above we drew attention to the temperature observations at Portland as being evidently too high. In the following February (1877) the mistake was rectified, and since then the observations of temperature at this station agree with those made at the other stations. A comparison shows that down to January 1877 the published temperatures at Portland were about 5°·0 too high. As regards the averages published since then, however, no allowance has been made down to December 1883 for this large error. The result is that while at the other stations of the colony the mean temperatures of the months since February 1877 rise above and fall below their averages as at other places, Portland all but uninterruptedly appears as very much below its average. Indeed, except the unusually warm months of September 1879 and February 1880, not one of the other forty-six months shows a temperature as high as the average. It is the more necessary to draw attention to this point seeing that the faulty mean temperatures of Portland still continue to appear in works on climatology, either in the text, or they have been used along with the means of other places, similarly faulty, in drawing the isothermals of the globe.

HABITS OF BURROWING CRAYFISHES IN THE UNITED STATES

On May 13, 1883, I chanced to enter a meadow a few miles above Washington, on the Virginia side of the Potomac, at the head of a small stream emptying into the river. It was between two hills, at an elevation of 100 feet above the Potomac, and about a mile from the river. Here I saw many clayey mounds covering burrows scattered over the ground irregularly both upon the banks of the stream and in the adjacent meadow, even as far as ten yards from the bed of the brook. My curiosity was aroused, and I explored several of the holes, finding in each a good-sized crayfish, which Prof. Walter Faxon identified as *Cambarus diogenes*, Girard (*C. obesus*, Hagen), otherwise known as the burrowing crayfish. I afterwards visited the locality several times, collecting specimens of the mounds and crayfishes, which are now in the United States National Museum, and making observations.

At that time of the year the stream was receding, and the meadow was beginning to dry. At a period not over a month previous, the meadows, at least as far from the stream as the burrows were found, had been covered with water. Those burrows near the stream were less than six inches deep, and there was a gradual increase in depth as the distance from the stream became greater. Moreover, the holes farthest from the stream were in nearly every case covered by a mound, while those nearer had either a very small chimney or none at all; and subsequent visits proved that at that time of year the mounds were just being constructed, for each time I revisited the place the mounds were more numerous.

The length, width, general direction of the burrows, and number of the openings were extremely variable, and the same is true of the mounds. Fig. 1 illustrates a typical burrow shown in section. Here the main burrow is very nearly perpendicular, there being but one oblique opening having a very small mound, and the main mound is somewhat wider than long. Occasionally the burrows are very tortuous, and there are often two or three extra openings, each sometimes covered by a mound. There is every conceivable shape and size in the chimneys, ranging from a mere ridge of mud, evidently the first foundation, to those with a breadth one-half the height. The typical mound is one which covers the perpendicular burrow in Fig. 1, its dimensions being six inches broad and four high. Two other forms are shown in Fig. 2. The burrows near the stream were seldom more than six inches deep, being nearly perpendicular, with an enlargement at the base, and always with at least one oblique opening. The mounds were usually of yellow clay, although in one place the ground was of fine gravel, and there the chimneys were of the same character. They were always circularly pyramidal in shape, the hole inside being very smooth, but the outside was formed of irregular nodules of clay hardened in the sun and lying just as they fell when dropped from the top of the mound. A small quantity of grass and leaves was mixed through the mound, but this was apparently accidental. The size of the burrows varied from half an inch to two inches in diameter, being smooth for the entire distance, and nearly uniform in width. Where the burrow was far distant from the stream, the upper part was hard and dry. In the deeper holes I invariably found several enlargements

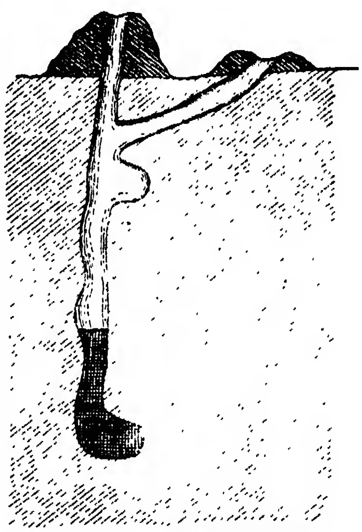

Fig. 1 Section of Crayfish burrow

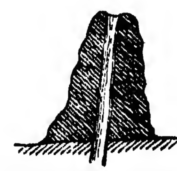

Fig. 2 Crayfish mound

Fig. 2 Crayfish mound

at various points in the burrow. Some burrows were three feet deep, indeed they all go down to water, and, as the water in the ground lowers, the burrow is undoubtedly projected deeper. The diagonal openings never at that season of the year have perfect chimneys, and seldom more than a mere rim. In no case did I find any connection between two different burrows. In digging after the inhabitants I was seldom able to secure a specimen from the deeper burrows, for I found that the animal always retreated to the extreme end, and when it could go no farther would use its claws in defence. Both males and females have burrows, but they were never found together, each burrow having but a single individual. There is seldom more than a pint of water in each hole, and this is muddy and hardly suitable to sustain life.

The neighbouring brooks and springs were inhabited by another species of crayfish, *Cambarus bartonii*, but although especial search was made for the burrowing species, in no case was a single specimen found outside of the burrows. *C. bartonii* was taken both in the swiftly-running portions of the stream, and in the shallow side pools, as well as in the springs at the head of small

The brook near where my observations were made was fast decreasing in volume, and would probably continue to do so until in July its bed would be nearly dry. During the wet seasons the meadow is itself covered. Even in the banks of the stream, then under water, there were holes, but they all extended obliquely without exception, there being no perpendicular burrows, and no mounds. The holes extended in about six inches, and there was never a perpendicular branch, nor even an enlargement at the end. I always found the inhabitant near the mouth, and by quickly cutting off the rear part of the hole could force him out, but unless forcibly driven out it would never leave the hole, not even when a stick was thrust in behind it. It was undoubtedly this species that Dr. Godman mentioned in his "Rambles of a Naturalist," and which Dr. Abbott (*Am. Nat.*, 1873, p. 81) refers to *C. bartonii*. Although I have no proof that this is so, I am inclined to believe that the burrowing crayfishes retire to the stream in winter, and remain there until early spring, when they construct their burrows for the purpose of rearing their young, and escaping the summer droughts. My reason for saying this is that I found one burrow which on my first visit was but six inches deep, and later had been projected to a depth at least twice as great, and the inhabitant was an old female.

I think that after the winter has passed, and while the marsh is still covered with water, impregnation takes place and burrows are immediately begun I do not believe that the same burrow is occupied for more than one year, as it would probably fill up during the winter. At first it burrows diagonally, and as long as the mouth is covered with water is satisfied with this oblique hole. When the water recedes, leaving the opening uncovered, the burrow must be dug deeper, and the economy of a perpendicular burrow must immediately suggest itself. From that time the perpendicular direction is preserved with more or less regularity. Immediately after the perpendicular hole is begun, a shorter opening to the surface is needed for conveying the mud from the nest, and then the perpendicular opening is made. Mud from this and also from the first part of the perpendicular burrow is carried out of the diagonal opening and deposited on the edge. If a freshet occurs before this rim of mud has a chance to harden, it is washed away and no mound is formed over the oblique burrow. After the vertical opening is made, as the hole is bored deeper, mud is deposited on the edge, and the deeper it is dug the higher the mound. I do not think that the chimney is a necessary part of the nest, but simply the result of digging. I carried away several mounds, and in a week revisited the place, and no attempt had been made to replace them; but in one case, where I had, in addition, partly destroyed the burrow by dropping mud into it, there was a simple half rim of mud around the edge, showing that the crayfish had been at work; and as the mud was dry the clearing must have been done soon after my departure. That the crayfish retreats as the water in the ground falls lower and lower. [illegible] for them to live in, and they must migrate. It would be interesting to know more about the habits of this peculiar species, about which so little has been written. An interesting point to settle would be how and where it gets its food. The burrow contains none, either animal or vegetable. Food must be procured at night, or when the sun is not shining brightly. In the spring and fall the green stalks of meadow grasses would furnish food, but when these become parched and dry they must either dig after and eat the roots, or search in the stream. I feel satisfied that they do not tunnel among the roots, for if they did so these burrows would be frequently met with. Little has as yet been published upon this subject, and that little covers only two spring months, April and May, and it would be interesting if those who have an opportunity to watch the species during other seasons, or who have observed them at any season of the year, would make known their results.

RALPH S. TARR

THE YOUNG GORILLA OF THE JARDIN DES PLANTES

THROUGH the courtesy of the editor of *La Nature* we are able to give an illustration from an instantaneous photograph of a young male gorilla obtained at the commencement of last winter by the Natural History Museum at Paris. It had been imported from the Gaboon, and it was the first living specimen of this great anthropomorphic ape which had been brought to France. Its study would have presented many points of interest, not alone from the Natural History point of view, but also from the opportunity it would have afforded of studying the development of its intellectual faculties. This young specimen was about three years of age, he had already his full complement of milk-teeth, and the long and sharp canines were decidedly longer than the molars. In disposition he appeared to be very different from either the orang-outan or the chimpanzee. While these in a state of captivity are mostly gentle and sociable, this young gorilla on the other hand was savage, morose, and brutal; he never gave his keeper the least mark of affection; he never allowed himself to be touched without evidencing the greatest aversion, and for the most part he returned caresses by snappings. He never took the least part in the games of the other apes, and he most reluctantly tolerated having them near him. He was but little active, and most generally kept himself crouched up in a corner of the cage, or sitting on a branch with his back up against the wall, and scarcely ever moved but to look about for something to eat. He used his hands with much readiness, and they were extremely well developed. His lips were less mobile than in the chimpanzee, especially the lower lip, which was never pouted out when drinking into a spoon-shaped form. His eyes were extremely mobile, and were crowned with immense superciliary ridges; his nose was flat, with excessively large nostrils, giving him a quite peculiar physiognomy.

His intelligence was feebly developed, and was in any case quite below that of the other anthropoid apes, or

even of the gibbons. Since the above note was presented by Alph. Milne-Edwards to the Paris Academy of Sciences the young gorilla died at the Jardin des Plantes.

NOTES

THE portrait of the late Sir William Siemens, which we give this week as one in our series of Scientific Worthies, belongs to the previous volume of NATURE, and is intended to accompany the memoir at p. 97.

THE Secretary of State for India has determined that India shall be represented at the forthcoming International Prime Meridian Conference at Washington, and has nominated as the India Office delegate Lieut.-General R. Strachey, C.S.I. Capt. Sir Fred. J. O. Evans, R.N., K.C.B., F.R.S., and Prof. J. C. Adams, F.R.S., on the recommendation of the Science and Art Department, have been appointed delegates to represent the United Kingdom at the Conference.

ON May 28, at an extraordinary meeting of the Vienna Academy of Sciences, Count Hans Wilczek was elected Honorary Member. In the Mathematical and Natural Science Section, Dr. Albrecht Schrauf, Professor of Mineralogy at the Vienna University, and Dr. Leopold Gegenbauer, Professor of Mathematics at the Innsbruck University, were elected Corresponding Members. As Foreign Honorary Members were elected Sir William Thomson, and Charles Hermite (Paris); as Foreign Corresponding Members, Prof. L. Leuckart (Leipzig), Prof. Edward Frankland, and Prof. Carl Nägeli (Munich).

THE "Rede" Lecture was delivered on Wednesday, last week, in the Cambridge University Senate House, by Mr. Francis Galton, M.A., F.R.S. Mr. Galton, who had selected as the subject for the lecture "The Measurement of Human Faculty," stated that, although it had been a matter of controversy whether a more complete measurement of man's capacity could be attained than was already discovered by means of examinations which measured intellectual capacity, yet he would endeavour to demonstrate that as the capacity of man, taken in its widest sense, including character and physique, was finite, therefore it was measurable. He pointed out that an important adjunct to the attempt to measure human faculty would be records containing particulars regarding eyesight, colour-sense, hearing, breathing capability, height, span of arms, &c. At the Johns Hopkins University in America physical education and hygiene were compulsory on all students, and although the physical measurements taken were not compulsory yet few objected, and the result was that the most valuable statistics were collected, and in many instances good advice given to the students in what way to counteract the effects of any abnormal condition observed, such as irregularity of muscular development. Mr. Galton concluded by suggesting that a laboratory should be opened at Cambridge to investigate this new science. The cost would be small; the result, he ventured to predict, would be large and beneficial, for, by the compiling of continuous records of health, growth, and disease, much useful knowledge would be acquired, and by a long series of observations on the lines he had indicated it would be possible to measure the human faculty as accurately as, if not more so than, our system of examinations measures the intellectual faculty.

WE understand that the Fishery Board for Scotland is anxious to have powers enabling it to remove obstructions which interfere with the ascent of salmon up several Scottish rivers. It is specially desirous to introduce as soon as possible a fishway at the falls, and this, when done, would open up some 500 miles of excellent fishing and spawning ground. Last week there were several interesting arrivals from fishery officers:—(1) A fine specimen of the "Opah fish" (*Lampris guttata*) was taken off Unst Island, Shetland, on May 22, and forwarded by the fishery officer to Prof. Ewart, University of Edinburgh. The fish, which measured 4 feet in length and over 2 feet in depth, has been handed over to Prof. Turner. This Opah will enable Prof. Turner to complete an account of the fish begun some years ago, when he received a somewhat smaller specimen from the Moray Firth. (2) A turbot with peculiar frontal process, an eye on each side of the head, both sides of the body equally dark, and provided with spines. (3) Mature sprats. It seems proved that sprats leave the estuaries in spring to spawn at sea. (4) Developing herring eggs. Taken along with similar specimens which have been arriving since October last, these show that herring spawn on the east coast from August until May, and not, as is usually supposed, only during August and September and during February and March.

IN response to the appeal of the Prince of Wales, as President of the City and Guilds of London Institute, the following contributions have been already promised to the General Fund and to the Equipment Fund of the Central Institution, Exhibition Road, by the undermentioned Companies:—Fishmongers, 4000*l.*; Mercers, 2000*l.*; Clothworkers, 2000*l.*; Corporation of London, 1000*l.*; Skinners, 1000*l.*, and an increased subscription of 500*l.* annually; Leather-sellers, 500*l.*; Carpenters, 500*l.*; Armourers and Braziers, 300*l.*; Tallow Chandlers, 105*l.*; Scriveners, 105*l.*; Stationers, 52*l.* 10*s.* annually; Clockmakers, 26*l.* 5*s.* The letter of the President is still under the consideration of the Courts of several Companies, and it is confidently expected that the sum required will be obtained.

A CORRESPONDENT writes:—"Last week you had occasion to refer to the little attention which is given in our schools to the study of geography, and the consequent withdrawal of certain medals which were awarded by the Royal Geographical Society to the most proficient candidates from the public schools. The superiority of our Continental neighbours in this matter will be apparent to any one who visits the Educational Section of the International Exhibition, which has been so well organised in the new Technical Schools by Mr. R. Cowper. Here a society of teachers, known as the Brothers of the Christian Schools, exhibit a number of hypsometrical wall maps and physical atlases admirably calculated to give correct notions of the real configuration of the earth's surface. There is also a collection of small models in relief, some of local topographical interest, and others of general utility as illustrating the definitions and leading facts of physical geography. These maps and reliefs were all made by a member of the Society—Brother Alexis—who has successfully striven, in France and Belgium, to introduce rational methods into the teaching of political and physical geography. The interest taken in this subject by students in the schools and colleges of the Brothers in France is shown by a large number of albums of maps sent in by them. It is interesting to notice that many of the local maps were drawn from surveys made by the students under the direction of their teachers. Such field-work is decidedly the best for advanced students, and is sure to be done *con amore*. A second collection sent from the Collegiate Schools of the same Society in Belgium will be found in the Belgian Court. The teachers of those of our public schools from which geography has not been absolutely ostracised will do well to carefully examine the physical maps and reliefs of the Brothers, as well as the cartographical work of their students. The result must be an improvement in our methods. If the Educational Exhibition does no more than raise the standard of geographical teaching throughout the country, it will have served a useful purpose."

IT is worthy of note that the General Assembly of the Free Church of Scotland have approved of the establishment of a Chair of Natural Science in their Glasgow Theological College.

THE Council of the Hartley Institute, Southampton, have issued a circular with reference to the Geological Survey of Hampshire and the Isle of Wight. The Council think that it would be of great service to the landowners and inhabitants of the county that the Geological Survey should now be revised on the map of the 6-inch scale. This revision of the work previously carried out on the old 1-inch map would enable many errors in detail in the former work to be corrected, and would give the county a much more valuable and detailed geological map, the sheet of which relating to any parish could be had separately by paying the cost of the map and the cost of colouring. At present this is not to be obtained, nor is it likely to be obtainable unless the Government can be induced to survey the county, geologically, on the map of the 6-inch scale as some other counties have been surveyed. This work, taking the old Survey as the basis, would not be expensive. The Hartley Council intend to request the members of the House of Lords connected with the county, and the representatives of the county and boroughs of Hampshire in the House of Commons, to urge the Government to revise the County Geological Survey upon the 6-inch map. We trust the Government will readily accede to the request; a minute revision of this geologically interesting district would be of great service to science.

ONE afternoon, *Science* states, during the recent cruise of the *Albatross* in the Caribbean Sea, several boobies were flying around the ship, and finally one of them alighted on the forecastle, when he was caught by one of the men, who, after amusing himself and his shipmates a while, tossed it overboard, expecting it would take itself off as quickly as possible; but, to their surprise, it returned immediately, alighting on the rail, where nearly every man of the crew had congregated to watch its performance. It did not seem to be distressed in any way, and went deliberately to work rearranging its plumage, which had been somewhat ruffled by handling, calmly surveying the noisy crowd of men gathered around it. They tried to feed it, offering everything that could be found, but nothing seemed to suit its taste. It would not submit quietly to being handled, but made no attempt to fly away; and, although tossed overboard six times during the afternoon, it returned as often, invariably alighting in the same place among the men, where it finally took up its quarters for the night, remaining till six o'clock the next morning, when it left without ceremony, and was not afterwards seen.

THE Esposizione Generale Italiana was opened at the end of April in Turin, and at the end of May the inauguration of the International Electrical Exhibition took place. Prof. Ferraris is the director of the International Department. A good display of meteorological instruments has been made in a tower belonging to the front monumental entrance. An inscription states that the Italians having inaugurated meteorology in the world are anxious to show the progress which this department of knowledge has made in its native country. The extent of the exhibition is about 1 kilometre by 450 metres on the banks of the Po, in the old gardens of Valentino Castle, where Beccaria executed his celebrated experiments on thunderstorm phenomena about 100 years ago.

A VIOLENT shock of earthquake occurred on the night of May 19 at the Island of Kishm, near the mouth of the Persian Gulf. No less than twelve villages were destroyed. Two hundred people were killed, and many others injured. Kishm is the largest island in the Persian Gulf, and is surrounded by many smaller islands. It is seventy miles long, and averages twelve miles broad. The population, chiefly Arabs, number about five thousand.

THE latest news from the Sagastyr Meteorological Station on the Lena, published by the St. Petersburg *Izvestia*, is dated November 25. The expedition remained to winter a second year, and will continue its observations until the present month. Last summer M. Eigner made the survey of two branches of the Lena, from the place where Capt. De Long landed on his sad journey. Dr. Bunge revisited the place where the Adams mammoth was found, and mapped also the place where De Long perished with his companions. The summer was altogether very cold, the average temperature of the three summer months being only $3^{\circ}\cdot25$ C. The sky was cloudy throughout, and fogs were nearly continuous. The lowest temperature observed last winter was on February 7, when the thermometer fell to $-52^{\circ}\cdot3$ C.

THE East of Scotland Union of Naturalists' Societies holds its first annual meeting at Dundee to-morrow and Saturday.

MR. ARCHIBALD BARR, B.Sc., C.E., "Young" Assistant to Dr. James Thomson, F.R.S., Professor of Civil Engineering and Mechanics in the University of Glasgow, has been appointed Professor of Civil and Mechanical Engineering in the Yorkshire College.

MR. W. PHILLIPS, F.L.S., of Shrewsbury, has in preparation "A Manual of the British Discomycetes, with Descriptions of all the Species of Fungi hitherto found in Britain, included in the Family, and Illustrations of the Genera."

THE last volume of the *Memoirs* of the Ethnographical Section of the Russian Geographical Society (vol. xii.) contains a rich collection of Russian folk-lore collected in the Samara province on the Volga, by D. N. Sadovnikoff.

THE additions to the Zoological Society's Gardens during the past week include a Himalayan Bear (*Ursus tibetanus*) from

North India, presented by Lieut. E. A. P. Hobday; three Black-eared Marmosets (*Hapale penicillata* ♂ ♂ ♂) from South-East Brazil, presented by Mr. H. F. Makins, F.Z.S.; a Purple-faced Monkey (*Semnopithecus leucoprymnus* ♀) from Ceylon, presented by Mr. J. W. Dring; a Common Heron (*Ardea cinerea*), British, presented by Mr. T. E. Gunn; a Leach's Laughing Kingfisher (*Dacelo leachi*) from Queensland, presented by Dr. Carl Lumholtz; a Laughing Kingfisher (*Dacelo gigantea*) from Australia, presented by Mr. E. R. Oliver; a Great Grey Shrike (*Lanius excubitor*), British, presented by Mr. J. Pratt, F.Z.S.,; a Spotted Bower Bird (*Chlamydodera maculata*) from Australia, presented by Lieut.-Col. W. Hill James; four River Frogs (*Rana fortis*) from Germany, presented by Mr. G. A. Boulenger, F.Z.S., a Green Turtle (*Chelone viridis*) from West Indies, presented by Mr. J. Wyan Thomas; a Tarantula Spider from Brazil, presented by Mr. C. A. Craven, C.M.Z.S.; a Common Boa (*Boa constrictor*) from South America, deposited; a Chimpanzee (*Anthropopithecus troglodytes* ♀), a Bosman's Potto (*Perodicticus potto* ♂) from West Africa, a Duyker-bok (*Cephalophus mergens* ♀) from South Africa, a Ring-tailed Coati (*Nasua rufa*) from South America, two Blood-stained Finches (*Carpodacus hæmorrhous*) from Mexico, a Snow Bunting (*Plectrophanes nivalis*), North European; an Angola Vulture (*Gypohierax angolensis*) from West Africa, a Guatemalan Amazon (*Chrysotis guatemalæ*) from Central America, four Elegant Grass Parrakeets (*Euphema elegans*) from South Australia, two Wild Ducks (*Anas boschas*), two Call Ducks (*Anas boschas*, var.), two Common Wigeon (*Mareca penelope*), two Common Pintails (*Dafila acuta*), six Common Teal (*Querquedula crecca*), two Muscovy Ducks *Coirina moschata*), European, two Mandarin Ducks (*Æx galericulata*) from China, purchased; a Common Wombat (*Phascolomys wombat*) from Tasmania, received in exchange.

OUR ASTRONOMICAL COLUMN

The Total Solar Eclipse of 1889, January 1.—The general circumstances of most of the total eclipses of the sun more or less available for physical observations before the close of the present century have been already described in this column: it remains, however, to make reference to that which will take place on January 1, 1889, and which will be total in the western part of the United States.

The central eclipse commences on the North Pacific Ocean in about longitude 178° E. and latitude 53° N.; it occurs with the sun on the meridian in 137° 57′ W. and 36° 42′ N., and ends in about 95° W. and 52° 15′ N. It strikes the American coast in the State of California in latitude 38° 50′, and the town of Hamilton, according to our approximate computation, would appear to be upon the central line: here the middle of totality occurs at 1h. 40m. 34s. local mean time, with the sun at an altitude of nearly 25°, and the duration of the total phase is 2m. 4s. The important observatory lately established on Mount Hamilton is outside of the zone of totality, the magnitude of the eclipse at that station being 0·98, and the middle at 1h. 45m. The following are points upon the line of central eclipse:—

Longitude	112 34 W.	Latitude	43 15 N.	Sun's altitude	15·9
„	106 14 „	„	46 15 „	„	10·2
„	100 21 „	„	49 9 „	„	5·0

It will be seen that the sun will set totally eclipsed on British territory after the total phase has crossed the Assiniboine River and the southern extremity of Lake Winnipeg.

The second total solar eclipse in 1889 was described in Nature in June 1877. It will be visible in Martinique, St. Lucia and Barbados, but with the sun at a low elevation, totality continuing about one minute and three-quarters, and will meet the coast of Africa in Angola in about 10° south latitude, where the total phase will have a duration of 3m. 30s., the sun at an altitude of 56°.

Variable Stars.—In 1859 Hencke of Driesen drew attention to a star in Carrington's Redhill Catalogue which he had found to be variable. It is No. 1902, and was observed on three nights in March and April 1856, the magnitude being twice noted 9·5 and once 10·5. Hencke had observed it 8m. at the time he wrote, but believed it had probably been invisible with his means for some years previously. His notice appears in Peters' *Zeitschrift für populare Mittheilungen aus dem Gebiete der Astronomie* &c., vol. i. p. 131. The star is not found in the catalogues of Fedorenko or Schwerd. Its approximate position for the beginning of 1885 is in R.A. 12h. 44m. 49s., N.P.D. 7° 39′·8.

At p. 150 of the Redhill Catalogue Carrington mentions that Oeltzen's No. 515, a seventh magnitude once observed by Schwerd had been looked for ineffectually. Oeltzen had re-examined his reduction of the observation which was made at Speyer on October 19, 1826, and found it correct. The star's place for 1885 is in R.A. 8h. 27m. 54s., N.P.D. 6° 52′·7. Close to this position there is a star in Fedorenko's catalogue from Lalande's observations (Nos. 1305-6) which is once called 8m., and once 5·6, the observations having been apparently made on March 19 and 20, 1790. It is 6m. in Groombridge, and 7m. in the *Durchmusterung* and in the Radcliffe Catalogue. Perhaps the discordance in Lalande's published estimates is occasioned by a misprint, and unfortunately there are several obvious errors of this kind in the catalogue deduced from his observations. The star in question is Groombridge 1431.

While writing upon polar variables we may once more refer to Bradley 396, R.A. (1885) 2h. 53m. 58s., N.P.D. 8° 58′·6, which, unless the existence of very improbable errors of estimation in the various catalogues is admitted, would appear to vary between the fifth and seventh magnitudes at the least, and there is a suspicion that the period may not be long.

A minimum of χ Cygni was due on May 22, and a maximum may be expected about November 16; from three determinations Schmidt found that the minimum preceded the maximum 178 days. The average period since 1877 has been 408½ days. The variable is the true χ (Bayer) Cygni, not the 17 Cygni of the catalogues.

GEOGRAPHICAL NOTES

The fifth fascicule of A. E. Nordenskjöld's "Popular Scientific Appendix to the Voyage of the *Vega*" ("Studier och Forskningar föranledda af mine resor i höga norden") will be most welcome to the general reader, and we hope it may be translated into English. It contains a profusely illustrated, lively sketch, by M. Hans Hildebrand, on art among lower primitive populations. The drawings of the Chukches are especially remarkable. Caravans of sledges drawn by reindeer or by dogs, hunting scenes, splitting drift-wood, and sea-hunting, are most interesting, and not the slightest mistake is possible as to what the Chukche artist intended to represent. The Chukches are as successful, too, in drawing subjects less known to them, such as the *Vega* at its winter-quarters, or two men of the crew exercising in fencing. The most remarkable piece is that given to Baron Nordenskjöld by Lord Walsingham, which is reproduced by means of photography. The original is drawn on walrus-skin, and represents on the borders of the skin the shores with their hills, Chukche settlements, and a variety of scenes from Chukche life on shore; while the interior contains a variety of scenes from sea-hunting, harpooned whales pretty well represented with their waterspouts, ships, boats, and so on. The Europeans, sometimes with umbrellas, sometimes fighting with Chukches, are perfectly recognisable. The engravings showing the carvings in bone that are made by Chukches and Esquimaux are also very interesting, whilst other drawings allow us to compare the Northern primitive art with the art of Boshmans and North American Indians. M. Hildebrand's remarks on the art of prehistoric man and his parallels with the Normannic drawings—also well illustrated—will be equally attractive to the general reader. The same fascicule contains the first pages of a paper on the life of insects in Arctic regions, by M. Christopher Aurivillius.

The *Bolletino* of the Italian Geographical Society for May contains a brief account of Signor Maurizio Buonfanti's late expedition across North Africa. The traveller, leaving Tripoli early in the month of April 1881, proceeded first in the direction of Lake Chad, mainly along the route already followed by Denham and Clapperton, Barth, Rohlfs, and other modern explorers. His chief object was to penetrate into the hitherto unexplored region stretching south from Adamawa, which territory was reached by the direct road from Kuka on Lake Chad through

Dikoa to Doloo. But a further advance in this direction was prevented by the disturbed state of the frontiers between Bornu and Adamawa. Buonfanti was consequently compelled to retrace his steps to Kuka, whence he turned westwards along the route recently opened by Lieut. Massari to Kano. After some trips to Yakoba and other little-known parts of Sokoto, he made his way through Gando to the Niger at Say, about midway between Timbuktu and the Binue confluence. Here he turned north, and for the first time *ascended* the Niger as far as Timbuktu. This feat, hitherto supposed to be impossible, was performed *in the dry season*, and the problem thus successfully solved possesses considerable geographical and commercial importance in connection with the attempts now being made to establish regular lines of water communication between Western and Central Sudan and the Gulf of Guinea. From Timbuktu the route lay through the States of Massina and Bambarra to the almost unknown territory of Tombo, the attempt to explore which region ended in disaster. Attacked in the Sanghi district by the natives, the expedition was plundered and almost completely dispersed, being reduced from an escort of 250 to six persons. Thus reduced to the greatest straits, the traveller was driven eastwards, and after enduring fearful sufferings reached the Bussanga country north of Dahomey. Here he fortunately came upon a Roman Catholic mission, which provided him with the means of continuing his journey southwards to the coast of Guinea. He arrived at Lagos on March 5, 1883, having lost all his scientific collections during the disastrous journey through Tembo.

We received last year complete reports of the state of the ice around Greenland, from Nordenskjöld, and in the Siberian Seas, from Hovgaard, but no report as to the conditions around Spitzbergen. As complete reports of the state and conditions of the ice in the various Arctic seas from year to year will greatly tend to assist glacialists in their researches and future Polar travellers, we publish some particulars furnished by the well-known Arctic hunter, Capt. M. E. Arnesen, of Tromsö, of his voyages in the Spitzbergen seas last summer:—Leaving Tromsö on April 21, he encountered the ice on April 28 in lat. 68° 28′ N. and long. 41° 18′ E. On May 4 the first seal was shot in lat. 68° 50′ N. and long. 42° 10′ E. A storm clearing the ice away, he was able to sail as far as 69°. Here a large ice-field stretched west-north-west as far as lat. 69° 55′ N. and 44° 30′ E., where it curved in a north-easterly and easterly direction. During the fifteen years Capt. Arnesen has sailed in the Arctic seas he never experienced such an early and warm spring. The heat was at times quite oppressive. On the night of July 14 he rounded South Cape at Spitzbergen. The ice lay towards Whales Point, close to the western shore. The Thousand Islands were on July 16 entirely surrounded with ice, stretching about a mile out to sea on the west side. From High Rocks an ice-field runs to the south-south-west. The wind was generally northerly and light, with alternating fogs and clear weather. Deicrow's Sound was entirely free from ice, but, at Black Point, passage between Halfmoon and the other islands was impossible. Encountering the ice on July 20, west of Whales Point, he found no change in its state. On July 22 the edge of the ice was lying from High Rocks to the southern point of Hope Island. For two days a thick fog prevailed. On July 24 the southern point of Hope Island was passed, where close ice stretched south-south-west. The wind was during this week slight, but came alternately from all quarters, sometimes with rain and fog. On July 28 the current set the ice southwards, so that the Thousand Islands were in open water, and towards Hope Island only a few floes were seen. The Halfmoon Islands were in clear water. On the 29th the wind fell, "ice-blink," *i.e.* the reflection of new ice in the sky, being seen to the eastward. On the 30th compact ice was encountered south of Ryk Vs's Islands. On July 31 Whales Point was found free from ice. On August 4 the country at the mouth of Walter Thymen Strait was perfectly free from ice, only old glaciers being visible on the mountains. The grass was quite out. The north-eastern part of Hans Foreland forms a great low plateau with good grazings for the reindeer, where large herds are found. The reindeer were in a very good condition, a circumstance which further proves the early and mild spring of last year. On the afternoon of August 6 the temperature in the shade was 12° C., and that of the surface of the water 9° C. On the night of the 17th a little snow fell in the mountains. An old ox, castrated and marked in the ear, was shot. It was believed to be one of those which escaped from Nordenskjöld at Mossel Bay in 1872. East of Hans Foreland and Barents Land there was then no trace of ice; in fact the sea ran mountains high on that side.

The last volume of the *Memoirs of the Russian Geographical Society* (vol. xii. No. 4) contains the "Memoirs of the Interpreter Otano Kigoro on Corea," translated from the Japanese by M. Dmitrevsky. The author was interpreter of the Corean language on the Tsousima Island, and compiled his book in 1794 on information gathered from Corean officials, as also from Chinese and Japanese works on Corea. The Russian translator of this book has added to it most valuable information gathered especially from the great Corean Code, published in 1785 (Da-dyang-tun-byang), which contains a detailed description of Corea, as well as from several other Chinese and European works, such as the "History of the Corean Church," by Dallet. The extracts from the Corean Code are especially numerous and of great value. The work of Kigoro contains interesting descriptions of the "Customs at the Court," the provincial administration, the geography of Corea, its inhabitants, their customs, habitations, food, and agriculture, as also notes on the Corean administration, army, and literature.

The last number of the Irkutsk *Izvestia* contains an interesting paper by Dr. Martianoff on his journeys in the north-eastern part of the Minusinsk district. In a note on antiquities in the basin of the Yenisei M. Bogolubsky mentions, among others, that on the Ouzynjoul gold-washings on a river of the same name belonging to the basin of the Abakan, implements consisting of a red copper nail, a marmor ring, and a knife and an arrow of bone, were found, together with bones of mammoth, rhinoceros, *Bos urus*, horse, antelope, wolf, and domestic animals, at a depth of from ten to thirteen feet. If implements from different levels were not confounded together, this find would surely be of great value. We notice also a note on a little-known subject, the "Scythic disease" among Aleutes and Kamchadales, by M. Grebnitzky, and another on the rapids of the Angara, with a map.

The prospects of a trade between Europe and Siberia, through the Kara Sea, do not seem to be cheering. According to a private correspondent in Moscow, the steamer *Dallmann*, built at the Vulcan Engineering Works, Stettin, for towing on the Yenisei, lies at the trading station, Strelka, 75 versts south of Yeniseisk, where also two iron lighters of 5000 poods carrying capacity, and a wooden one capable of carrying 2000 poods, as well as two steam launches, now are. They are all to be sold, along with the buildings, depots, and factories at Strelka and the stations not far from the mouth of the Yenisei, about 800 versts north of Turukhansk. At the latter station large quantities of wheat, rye, and oats have been collected with a view to being exported to Europe. There seems at present little probability of their ever reaching their destination. During the last five or six years the steamer *Louise* has only twice succeeded in reaching the Yenisei and returning with cargo to Europe; three times the vessel failed in the attempt.

The last issue of the *Journal of the Ceylon Branch of the Royal Asiatic Society* (Colombo, 1883) is wholly occupied by a translation of that part of Ibn Batuta's travels relating to Ceylon and the Maldive Islands, accompanied by notes. The account of the customs of the primitive inhabitants of the Maldives is especially interesting.

ON THE NOMENCLATURE, ORIGIN, AND DISTRIBUTION OF DEEP-SEA DEPOSITS[1]

III.

It remains now to point out the area occupied by the red clay. We have seen how it passes at its margins into organic calcareous oozes, found in the lesser depths of the abysmal regions, or into the siliceous organic oozes or terrigenous deposits. In its typical form the red clay occupies a larger area than any of the other true deep-sea deposits, covering the bottom in vast regions of the North and South Pacific, Atlantic, and Indian Oceans. As above remarked, this clay may be said to be universally distributed over the floor of the oceanic basins; but it only appears as a true deposit at points where the siliceous and calcareous organisms do not conceal its proper characters.

Having now indicated its distribution, we must consider the mode of its formation, and give, in addition, a concise descrip-

[1] A Paper read before the Royal Society of Edinburgh by John Murray and A. Renard. Communicated by John Murray. Continued from p. 117.

tion of the minerals and of the organic remains which are commonly associated with it. The origin of these vast deposits of clay is a problem of the highest interest. It was at first supposed that these sediments were composed of microscopic particles arising from the disintegration of the rocks by rivers and by the waves on the coasts. It was believed that the matters held in suspension were carried far and wide by currents, and gradually fell to the bottom of the sea. But the uniformity of composition presented by these deposits was a great objection to this view. It could be shown, as we have mentioned above, that mineral particles, even of the smallest dimensions, continually set adrift upon disturbed waters must, owing to a property of sea water, eventually be precipitated at no great distance from land. It has also been supposed that these argillaceous deposits owe their origin to the inorganic residue of the calcareous shells which are dissolved away in deep water, but this view has no foundation in fact. Everything seems to show that the formation of the clay is due to the decomposition of fragmentary volcanic products, whose presence can be detected over the whole floor of the ocean.

These volcanic materials are derived from floating pumice and volcanic ashes ejected to great distances by terrestrial volcanoes, and carried far by the winds. It is also known that beds of lava and of tufa are laid down upon the bottom of the sea. This assemblage of pyrogenic rocks, rich in aluminous silicates, decomposes under the chemical action of the water, and gives rise, in the same way as do terrestrial volcanic rocks, to argillaceous matters, according to reactions which we can always observe on the surface of the globe, and which are too well known to need special mention here.

The detailed microscopic examination of hundreds of soundings has shown that we can always demonstrate in the argillaceous matter the presence of pumice, of lapilli, of silicates, and other volcanic minerals in various stages of decomposition.

As we have shown in another paper,[1] the deposit most widely distributed over the bed of modern seas is due to the decomposition of the products of the internal activity of the globe, and the final result of the chemical action of sea water is seen in the formation of this argillaceous matter, which is found everywhere in deep-sea deposits, sometimes concealed by the abundance of siliceous or calcareous organisms, sometimes appearing with its own proper characteristics associated with mineral substances, some of which allow us to appreciate the extreme slowness of its formation, or whose presence corroborates the theory advanced to explain its origin.

In the places where this red clay attains its most typical development, we may follow, step by step, the transformation of the volcanic fragments into argillaceous matter. It may be said to be the direct product of the decomposition of the basic rocks, represented by volcanic glasses, such as hyalomelan and tachylite. This decomposition, in spite of the temperature approximating to zero (32° F.), gives rise, as an ultimate product, to clearly crystallised minerals, which may be considered the most remarkable products of the chemical action of the sea upon the volcanic matters undergoing decomposition. These microscopic crystals are zeolites lying free in the deposit, and are met with in greatest abundance in the typical red clay areas of the Central Pacific. They are simple, twinned, or spheroidal groups, which scarcely exceed half a millimetre in diameter. The crystallographic and chemical study of them shows that they must be referred to Christianite. It is known how easily the zeolites crystallise in the pores of eruptive rocks in process of decomposition; and the crystals of Christianite, which we observe in considerable quantities in the clay of the centre of the Pacific, have been formed at the expense of the decomposing volcanic matters spread out upon the bed of that ocean.

In connection with this formation of zeolites, reference may be made to a chemical process whose principal seat is the red clay areas, and which gives rise to nodules of manganiferous iron. This substance is almost universally distributed in oceanic sediments, yet it is not so much of the areas of its abundance that we intend to speak as to the fact of its occurrence in the red clay, because this association tends to show a common relation of origin. It is exactly in those regions where there is an accumulation of pyroxenic lavas in decomposition, containing silicates with a base of manganese and iron, such for example as augite, hornblende, olivine, magnetite, and basic glasses, that manganese nodules occur in greatest numbers. In the regions where the sedimentary action, mechanical and organic, is, as it were, suspended, and where, as will appear in the sequel, everything shows an extreme slowness of deposition,—in these calm waters favourable to chemical reactions, ferro-manganiferous substances form concretions around organic and inorganic centres.

These concentrations of ferric and manganic oxides, mixed with argillaceous materials whose form and dimensions are extremely variable, belong generally to the earthy variety or wad, but pass sometimes, though rarely, into varieties of hydrated oxide of manganese with distinct indications of radially fibrous crystallisation. The interpretation to which we are led, in order to explain this formation of manganese nodules, is the same as that which is admitted in explanation of the formation of coatings of this material on the surface of terrestrial rocks. These salts of manganese and iron, dissolved in water by carbonic acid, then precipitated in the form of carbonate of protoxide of iron and manganese, become oxidised, and give rise in the calm and deep oceanic regions to more or less pure ferro-manganiferous concretions. At the same time it must be admitted that rivers may bring to the ocean a contribution of these same substances.

Among the bodies which, in certain regions where red clay predominates, serve as centres for these manganiferous nodules, are the remains of Vertebrates. These remains are the hardest parts of the skeleton—tympanic bones of whales, beaks of Ziphius, teeth of sharks; and just as the calcareous shells are eliminated in the depths, so all the remains of the larger Vertebrates are absent, except the most resistant portions. These bones often serve as a centre for the manganese iron concretions, being frequently surrounded by layers several centimetres in thickness. In the same dredgings in the red clay areas some sharks' teeth and Cetacean ear-bones, some of which belong to extinct species, are surrounded with thick layers of the manganese, and others with merely a slight coating. We will make use of these facts to establish the conclusions which terminate this paper.

In these red clays there occur in addition the greatest number of cosmic metallic spherules, or chondres, the nature and characters of which we have pointed out elsewhere.[1] We merely indicate their presence here, as we will support our conclusions by a reference to their distribution.

Reviewing, then, the distribution of oceanic deposits, we may summarise thus:—

(1) The terrigenous deposits, the blue muds, green muds and sands, red muds, volcanic muds and sands, coral muds and sands, are met with in those regions of the ocean nearest to land. With the exception of the volcanic muds and sands, and coral muds and sands around oceanic islands, these deposits are found only lying along the borders of continents and continental islands, and in inclosed and partially inclosed seas.

(2) The organic oozes and red clay are confined to the abysmal regions of the ocean basins; a Pteropod ooze is met with in tropical and subtropical regions in depths less than 1500 fathoms, a Globigerina ooze in the same regions between the depths of 500 and 2800 fathoms, a Radiolarian ooze in the central portions of the Pacific at depths greater than 2500 fathoms, a Diatom ooze in the Southern Ocean south of the latitude of 45° south, a red clay anywhere within the latitudes of 45° north and south at depths greater than 2200 fathoms.

Conclusions.—All the facts and details enumerated in the foregoing pages point to certain conclusions which are of considerable geological interest, and which appear to be warranted by the present state of our investigations.

We have said that the debris carried away from the land accumulates at the bottom of the sea before reaching the abysmal regions of the ocean. It is only in exceptional cases that the finest terrigenous materials are transported several hundred miles from the shores. In place of layers formed of pebbles and clastic elements with grains of considerable dimensions, which play so large a part in the composition of emerged lands, the great areas of the ocean basins are covered by the microscopic remains of pelagic organisms, or by the deposits coming from the alteration of volcanic products. The distinctive elements that appear in the river and coast sediments are, properly speaking, wanting in the great depths far distant from the coasts. To such a degree is this the case that in a great number of soundings, from the centre of the Pacific for example, we have not been able to distinguish mineral particles on which the mechanical action of water had left its imprint, and quartz is so rare that it may be said to be absent. It is sufficient to indicate these facts in order to make apparent the profound differences which separate the de-

[1] "On Cosmic and Volcanic Dust," *Proc. Roy. Soc. Edin.*, 1883-84.

[1] "On Cosmic and Volcanic Dust," *Proc. Roy. Soc. Edin.*, 1883-84.

posits of the abysmal areas of the ocean basins from the series of rocks in the geological formations. As regards the vast deposits of red clay, with its manganese concretions, its zeolites, cosmic dust, and remains of Vertebrates, and the organic oozes which are spread out over the bed of the Central Pacific, Atlantic, and Indian Oceans, have they their analogues in the geological series of rocks? If it be proved that in the sedimentary strata the pelagic sediments are not represented, it follows that deep and extended oceans like those of the present day cannot formerly have occupied the areas of the present continents, and as a corollary the great lines of the ocean basins and continents must have been marked out from the earliest geological ages. We thus get a new confirmation of the opinion of the permanence of the continental areas.

But without asserting in a positive manner that the terrestrial areas and the areas covered by the waters of the great ocean basins have had their main lines marked out since the commencement of geological history, it is, nevertheless, a fact, proved by the evidence derived from a study of the pelagic sediments, that these areas have a great antiquity. The accumulation of sharks' teeth, of the ear-bones of Cetaceans, of manganese concretions, of zeolites, of volcanic material in an advanced state of decomposition, and of cosmic dust, at points far removed from the continents, tend to prove this. There is no reason for supposing that the parts of the ocean where these Vertebrate remains are found are more frequented by sharks or Cetaceans than other regions where they are never or only rarely dredged from the deposits at the bottom. When we remember also that these ear-bones, teeth of sharks, and volcanic fragments, are sometimes incrusted with two centimetres of manganese oxide, while others have a mere coating, and that some of the bones and teeth belong to extinct species, we may conclude with great certainty that the clays of these oceanic basins have accumulated with extreme slowness. It is indeed almost beyond question that the red clay regions of the Central Pacific contain accumulations belonging to geological ages different from our own. The great antiquity of these formations is likewise confirmed in a striking manner by the presence of cosmic fragments, the nature of which we have described ("On Cosmic and Volcanic Dust," *Proc. Roy. Soc. Edin.*). In order to account for the accumulation of all the substances in such relatively great abundance in the areas where they were dredged, it is necessary to suppose the oceanic basins to have remained the same for a vast period of time.

The sharks' teeth, ear-bones, manganese nodules, altered volcanic fragments, zeolites, and cosmic dust are met with in greatest abundance in the red clays of the Central Pacific, at that point on the earth's surface farthest removed from continental land. They are less abundant in the Radiolarian ooze, are rare in the Globigerina, Diatom, and Pteropod oozes, and they have been dredged only in a few instances in the terrigenous deposits close to the shore. These substances are present in all the deposits, but owing to the abundance of other matters in the more rapidly forming deposits their presence is masked, and the chance of dredging them is reduced. We may then regard the greater or less abundance of these materials, which are so characteristic of a true red clay, as being a measure of the relative rate of accumulation of the marine sediments in which they lie. The terrigenous deposits accumulate most rapidly, then follow in order Pteropod ooze, Globigerina ooze, Diatom ooze, Radiolarian ooze, and, slowest of all, red clay.

From the data now advanced, it appears possible to deduce other conclusions important from a geological point of view. In the deposits due essentially to the action of the ocean, we are at once struck by the great variety of sediments which may accumulate in regions where the external conditions are almost identical. Again, marine faunas and floras, at least those of the surface, differ greatly, both with respect to species and to relative abundance of individuals, in different regions of the ocean; and as their remains determine the character of the deposit in many instances, it is legitimate to conclude that the occurrence of organisms of a different nature in several beds is not an argument against the synchronism of the layers which contain them.

The small extent occupied by littoral formations, especially those of an arenaceous nature, shown by our investigations, and the relatively slow rate at which such deposits are formed along a stable coast, are matters of importance.

In the present state of things there does not appear to be anything to account for the enormous thickness of the clastic sediments making up certain geological formations, unless we consider the exceptional cases of erosion which are brought into play when a coast is undergoing constant elevation or subsidence.

Great movements of the land are doubtless necessary for the formation of thick beds of transported matter like sandstones and conglomerates.

In this connection may be noted the fact that in certain regions of the deep sea no appreciable formation is now taking place. Hence the absence, in the sedimentary series, of a layer representing a definite horizon must not always be interpreted as proof either of the emergence of the bottom of the sea during the corresponding period, or of an ulterior erosion. Arenaceous formations of great thickness require seas of no great extent and coasts subject to frequent oscillations, which permit the shores to advance and retire. Along these, through all periods of the earth's history, the great marine sedimentary phenomena have taken place.

The continental geological formations, when compared with marine deposits of modern seas and oceans, present no analogues to the red clays, Radiolarian, Globigerina, Pteropod, and Diatom oozes. On the other hand, the terrigenous deposits of our lakes, shallow seas, inclosed seas, and the shores of the continents, reveal the equivalents of our chalks, greensands, sandstones, conglomerates, shales, marls, and other sedimentary formations. Such formations as certain Tertiary deposits of Italy, Radiolarian earth from Barbados, and portions of the Chalk where pelagic conditions are indicated, must be regarded as having been laid down rather along the border of a continent than in a true oceanic area. On the other hand, the argillaceous and calcareous rocks recently discovered by Dr. Guppy in the upraised coral islands in the Solomon Group are nearly identical with the Pteropod and Globigerina oozes of the Pacific.

Regions situated similarly to inclosed and shallow seas and the borders of the present continents appear to have been, throughout all geological ages, the theatre of the greatest and most remarkable changes; in short, all, or nearly all, the sedimentary rocks of the continents would seem to have been built up in areas like those now occupied by the terrigenous deposits, which we may designate "*the transitional or critical area of the earth's surface.*" This area occupies we estimate, about two-eighths of the earth's surface, while the continental and abysmal areas occupy each about three-eighths.

During each era of the earth's history the borders of some lands have sunk beneath the sea and been covered by marine sediments, while in other parts the terrigenous deposits have been elevated into dry land, and have carried with them a record of the organisms which flourished in the sea of the time. In this transitional area there has been throughout a continuity of geological and biological phenomena.

From these considerations it will be evident that the character of a deposit is determined much more by distance from the shore of a continent than by actual depth; and the same would appear to be the case with respect to the fauna spread over the floor of the present oceans. Dredgings near the shores of continents, in depths of 1000, 2000, or 3000 fathoms, are more productive both in species and individuals than dredgings at similar depths several hundred miles seawards. Again, among the few species dredged in the abysmal areas furthest removed from land, the majority show archaic characters, or belong to groups which have a wide distribution *in time* as well as over the floor of the present oceans. Such are the Hexactinellida, Brachiopoda, Stalked Crinoids and other Echinoderms, &c.

As already mentioned, the transitional area is that which now shows the greatest variety in respect to biological and physical conditions, and in past time it has been subject to the most frequent and the greatest amount of change. The animals now living in this area may be regarded as the greatly modified descendants of those which have lived in similar regions in past geological ages, and some of whose ancestors have been preserved in the sedimentary rocks as fossils. On the other hand, many of the animals dredged in the abysmal regions are most probably also the descendants of animals which lived in the shallower waters of former geological periods, but descended into deep water to escape the severe struggle for existence which must always have obtained in those depths affected by light, heat, motion, and other conditions. Having found existence possible in the less favourable and deeper water, they may be regarded as having slowly spread themselves over the floor of the ocean, but without undergoing great modifications, owing to the extreme uniformity of the conditions and the absence of competition. Or we may suppose that, in the depressions which

have taken place near coasts, some species have been gradually carried down to deep water, have accommodated themselves to the new conditions, and have gradually migrated to the regions far from land. A few species may thus have migrated to the deep sea during each geological period. In this way the origin and distribution of the deep-sea fauna in the present oceans may in some measure be explained. In like manner, the pelagic fauna and flora of the ocean is most probably derived originally from the shore and shallow water. During each period of the earth's history a few animals and plants have been carried to sea, and have ultimately adopted a pelagic mode of life.

Without insisting strongly on the correctness of some of these deductions and conclusions, we present them for the consideration of naturalists and geologists, as the result of a long, careful, but as yet incomplete, investigation.

THE FIXED STARS[1]

THERE is no science which has so long and so continuously occupied the thoughtful minds of successive generations of men as has astronomy; and of its various branches there is one which has for all ages possessed a special fascination, viz. that of sidereal astronomy.

There has ever been a desire to burst aside the constraints imposed upon our research by the distances of space, to pass from the study of the planets of our solar system to that of the suns and galaxies that surround us, to determine the position and relative importance of our own system in the scheme of the universe and the whence we have come and the whither we are drifting through the realms of space.

Questions without number crowd upon the mind. The galaxy or Milky Way—what is it? Is our sun one of its members? What is the shape of that galaxy? What are its dimensions? What is the position of our sun in it?

The star-clusters—what are they, these wondrous aggregations where hundreds and even thousands of suns may be seen in the limited field of view of a powerful telescope? Are these clusters galaxies? Have these suns real dimensions comparable with those of our sun, and is it distance alone that renders their light and dimension so insignificant to the naked eye? Or are the real dimensions of the clusters small as compared with our galaxy? Are their component suns but the fragments of some great sun that has been shattered by forces unknown to us, or have they originated from chaotic matter, which, instead of forming one great whirlpool and condensing by vortex action into one great sun, has been disturbed into numerous minor vortices, and so become rolled up into numerous small suns?

The nebulæ—what are they? Are they too condensing into clusters or stars, or will their ghost-like forms remain for ever unchanged amongst the stars? or do they play some part in the scheme of nature of which we have as yet no conception?

These and many others are the questions which press on the ardent mind that contemplates the subject; and there arises the intense desire to answer such questions, and where facts are wanting to supply facts by fancy. The history of deep and profound thought in some of these subjects goes back through 2000 years, but the history of real progress is but as of yesterday. The foundation of sidereal astronomy may be said to have begun with the art of accurate observation. Bradley's meridian observations at Greenwich about 1750, his previous discovery of the aberration of light in 1727, and Herschel's discovery of the binary nature of double stars, his surveys of the heavens, and his catalogues of double stars—these are solid facts, facts that have contributed more to the advancement of sidereal astronomy than all the speculations of preceding centuries. They point to us the lesson that "art is long and life is short," that human knowledge, in the slow developing phenomena of sidereal astronomy, must be content to progress by the accumulating labours of successive generations of men, that progress will be measured for generations yet to come more by the amount of honest, well-directed and systematically-discussed observation than by the most brilliant speculation, and that in observation concentrated systematic effort on a special thoughtfully-selected problem will be of more avail than the most brilliant but disconnected work.

I hope that no one present thinks from what I have said that I undervalue the imaginative fervid mind that longs for the truth, and whose fancy delights to speculate on these great subjects. On the contrary, I think and I believe that without that fervid mind, without that longing for the truth, no man is fitted for the work required of him in such a field—for it is such a mind and such desires that alone can sweeten the long watches of the night, and transform such work from drudgery into a noble labour of love.

It is for like reasons that I ask you to leave with me the captivating realms of fancy this evening, and to enter the more substantial realms of fact. And if at any time I should become too technical or dry I beg that you too will remember the noble problems for the solution of which such dry work is undertaken.

We suppose ourselves then face to face with all the problems of sidereal astronomy to which I have hastily referred—the human mind is lost in speculation, and we are anxious to establish a solid groundwork of fact.

Now what in such circumstances would be the instinct of the scientific mind?

The answer is unquestionable—viz. to measure—and no sooner were astronomical instruments made of reasonable exactness than astronomers did begin to measure, and to ask, are the distances of the fixed stars measurable?

I should like to have given a short history of the early attempts of astronomers to measure the distance of a fixed star. I had indeed prepared such an account, but I remembered that there is in this theatre a relentless clock that has curbed the exuberant verbosity of many a lecturer before me, and I found that if the real subject-matter of this evening's lecture were to be reached and dealt with before 10 o'clock, I must pass over this earlier history, instructive and interesting though it is, and come at once to the time when the long baffled labours of astronomers began to be crowned with success.

Perhaps I cannot summarise it better than in the words of Sir John Herschel. In one of his presidential addresses he says:—"The distance of every individual body in the universe from us is necessarily admitted to be finite. But though the distance of each particular star be not in strictness infinite, it is yet a real and immense accession to our knowledge to have *measured* it in any one case. To accomplish this has been the object of every astronomer's highest aspirations ever since sidereal astronomy acquired any degree of precision. But hitherto it has been an object which, like the fleeting fires that dazzle and mislead the benighted wanderer, has seemed to suffer the semblance of an approach only to elude his seizure when apparently just within his grasp, continually hovering just beyond the limits of his distinct apprehension, and so leading him on in hopeless, endless, and exhausting pursuit."

Those who have read the history of exact astronomy from the days of Flamsteed—*i.e.* from 1689—down to 1832, will understand how exactly these words of Sir John Herschel describe the position of the problem.

But these laborious pursuits, like all honest researches in quest of truth, were not without reward, even though the immediate object in view was not attained. Bradley was rewarded by his great discovery of aberration, and Sir William Herschel by the greatest of his great discoveries, the binary nature of double stars, when engaged in vain attempts to measure the distance of a fixed star. Time forbids that I should tell more of this instructive story—for the story of failure is often fully as instructive as that of success—and I must begin the history of our problem between 1832 and 1842, when success was first attained.

But before I begin it will save both time and circumlocution if I define a word that we must frequently use—viz. the word parallax.

Here on the table is a large ball representing the sun, and here, travelling on a circular railway round the larger ball, is a smaller ball which we shall suppose to represent the earth. The larger ball is suspended from the ceiling by a white string, the small ball is suspended from the same point by a red string. At the far end of the white string you can suppose a star whose true direction is represented by this white string, and whose apparent direction as looked at from the earth is represented by the red string. Now if the star is within a measurable distance, the red string which indicates the star's apparent direction as seen from the earth will always be displaced inwards towards the sun. This displacement is called "parallax." It may be defined as the change in the apparent place of a star produced by viewing it from a point other than that of reference. Our point of reference for stars is the sun, and as we view the stars now from one side of the sun, and six months afterwards from a point on the

[1] Lecture on Friday evening, May 23, at the Royal Institution, "On Recent Researches on the Distances of the Fixed Stars, and on some Future Problems in Sidereal Astronomy," by David Gill, LL.D., F.R.S., Her Majesty's Astronomer at the Cape of Good Hope.

opposite side of the sun—that is, from two points 186 millions of miles apart—we might expect to find a considerable change in their apparent places.

But previous to 1832 astronomers could not discover with any certainty that such changes were sensible—that, in other words, the red and the white strings met at a point so distant that, as far as they were able to measure, the two strings were practically parallel—or, putting it another way, the stars were so distant that the diameter of the earth's orbit viewed from the nearest star subtended a smaller angle than their instruments could measure. Bradley felt sure that if the star γ Draconis were so near that its parallax amounted to 1″ of arc he would have detected it—that is, if the earth's orbit viewed from γ Draconis measured 2″ in diameter, that is, if it looked as big as a globe one foot in diameter would look if viewed at forty miles distant, he would have detected it. But the real distances of the stars were greater than that.

The time at last arrived when the two great masters of modern practical astronomy, Bessel and Struve, were preparing by elaborate experiment and study for the researches which led to ultimate success. After vain attempts to obtain conclusive results by endeavours to determine the apparent changes in the absolute direction of a star at different seasons of the year, both astronomers had recourse to a method which, originally proposed by Galileo in 1632, was carried out first on a large scale by Sir William Herschel. I shall refer in the first place to the researches of the great Russian astronomer Struve.

Astronomers had sufficiently demonstrated that the distances of the stars were very great, and it was reasonable to argue that as a rule the brighter stars would be those nearest to us. If, therefore, two stars are apparently near each other—the one bright, the other faint—the chances are that in reality they are far apart, though accidentally nearly in a line.

Fig. 1.

If two such stars are represented by S *s* in Diagram I., they would appear near each other viewed from one side of the earth's orbit at A, but not so near each other viewed from B, the opposite side of the earth's orbit, the red lines obviously indicating the apparent angle between the stars when they are viewed from A, and the black lines the apparent angle when they are viewed from B. Struve selected for the star S the bright star Vega (α Lyræ). From its brilliancy he considered it probably one of our nearest neighbours amongst the stars, and a faint star apparently near it seemed to afford a suitable representative of the really distant star *s*. Struve was careful to ascertain that this comparison star was not physically connected with α Lyræ, and he was able to prove this from the fact that whilst α Lyræ has a small annual motion relative to all neighbouring stars, this motion is not shared by the faint comparison star. Struve was provided with a telescope driven by clockwork to follow the diurnal motion of a star, and thus the hands of the observer were free to make the necessary measures. These were accomplished by an instrument such as I hold in my hands applied to the telescope. This micrometer contains two parallel spider webs each attached to a slide, one slide being moved by one screw, the other by the other screw. The screws are provided with drum-heads divided into 100 parts. One web was placed on the image of α Lyræ, the other upon that of the faint comparison star, and the angle between the stars was thus read off in terms of the number of revolutions and decimals of a revolution of the screws. A number of such observations was made on each night, and the result for each night depended on the mean of the numerous observations made each night.

By observations on ninety-six nights between November 1835 and August 1838, he showed that the distance between α Lyræ and the faint comparison star changed systematically with a regular annual period, and that the maxima and minima of those distances corresponded with the times of the year at which these maxima and minima should occur if the brighter star were really much nearer than the fainter one.

Assuming that the fainter star is at a practically immeasurable distance, Struve showed that α Lyræ had a parallax that amounted to about a quarter of a second of arc, which is equivalent to the statement that a globe whose diameter is equal to that of the earth's orbit—that is, to 186,000,000 of miles—would at the distance of α Lyræ present an apparent diameter of half a second of arc. If you wish to realise this angle, place a globe one foot in diameter at a distance of eighty miles, or look at a coin half the diameter of a silver threepenny piece at a distance of one mile from the eye, and try to measure it.

The great German astronomer, Bessel, was simultaneously engaged in like work at Königsberg. He selected as the object of his researches a very remarkable double star—61 Cygni.

This star had already been the subject of similar researches on his part with much inferior means. He now attacked the problem with the splendid heliometer which had been made for him by Frauenhofer for the purpose. The principle of this instrument I shall presently explain. His reasons for choosing 61 Cygni were that the two components of this star, though not remarkable for brightness—they are just visible to the naked eye—yet have this peculiarity, that they have a remarkably large proper motion, the largest then known, though now surpassed by that of two other stars which I shall afterwards mention. They have an apparent angular motion relative to other stars of more than five seconds of arc per annum.

Struve had argued that if the stars were on the average of similar brightness, those stars which were brightest would probably be those nearest to us, and Bessel, in like manner, argued that if the absolute motions of the stars were similar on the average, those motions which appeared the largest belonged to stars which on the average were nearest to us—just as the motion of a snail could be easily watched at the distance of two or three feet from the eye, but could not be detected except after a long interval, if the animal were a good many yards distant.

Bessel employed two faint comparison stars at right angles to each other with respect to 61 Cygni, and he made two separate series of observations, the first extending from August 1837 to October 1838, the second from October 1838 to March 1840.

Both series confirm each other, and the results deduced separately from the measures of the two comparison stars also agree within very narrow limits. From all the observations combined Bessel found the parallax of 61 Cygni to be 35/100 of a second—a quantity which has been shown by the modern researches of Prof. Auwers and Dr. Ball to be more nearly half a second of arc. Thus at 61 Cygni the diameter of the earth's orbit round the sun would appear of the same size as a globe a foot in diameter viewed at forty miles distance, or of a silver threepenny piece a mile off. But whilst these great masters of astronomy—Struve and Bessel—had been exhausting the resources of their skill in observation, and that of the astronomical workshops of Europe in supplying them with the most refined instruments, a quiet and earnest man had been at work at the Cape of Good Hope, and, without knowing it at the time, had *really made the* FIRST *observations* which afforded strong presumptive evidence of the existence of the parallax of any fixed star.

Henderson occupied the post of Her Majesty's Astronomer at the Cape of Good Hope in 1832 and 1833, and during his brief and brilliant tenure of office there he made, amongst many others, a fine series of meridian observations of α Centauri—a bright and otherwise remarkable double star. When, after his return to England, Henderson reduced these observations, and compared them with the earlier observations of other astronomers, he found that α Centauri had a large proper motion; he was therefore led to examine and see whether his observations gave any indication of an annual parallax. He found that they did so, and not of a small parallax but of one amounting to nearly a second of arc. But it was not till this was confirmed, not only by the observations with the mural circle but by those of the transit instrument also, not only by his own observations but by those of Lieut. Meadows, his assistant, that Henderson ventured to publish his remarkable result.

In the year 1842 it was felt by the astronomical world at large that the problem which hitherto had baffled astronomers had begun to yield, that some approximation to the truth had at last been arrived at with regard to the distance of a fixed star, and it was fit and proper that the Royal Astronomical Society

of London should acknowledge the labours of him who had most effectually contributed to this end.

Henderson's results seemed sufficiently convincing, but they depended upon determinations of the absolute place of α Centauri. The experiences of the skilful astronomer Brinkley at Dublin were still fresh in the minds of astronomers. He had arrived by similar though less perfect means at results like those of Henderson; but his results had been proved to be fallacious, though the causes of their being so still remain somewhat inexplicable. In the case of Struve's observations the weight of evidence which he produced and the excellence of his method were admitted, but men were not prepared by experience for accepting as accurate the minute changes of angle which Struve had to measure—nor, I am bound to admit, was the proof afforded by Struve's series of observations so entirely convincing as that afforded by the series of Bessel. Therefore to Bessel the well-earned medal was given, but the labours of Struve and Henderson received high and honourable mention. I quote from the speech of Sir John Herschel in awarding that medal. He says of Henderson's researches on α Centauri:—

"Should a different eye and a different circle continue to give the same result, we must of course acquiesce in the conclusion; and the distinct and entire merit of the *first* discovery of the parallax of *a* fixed star will rest indisputably with Mr. Henderson. At present, however, we should not be justified in anticipating a decision which time alone can stamp with the seal of absolute authority."

So much for Sir John Herschel's officially expressed opinion. I can state now, and as Henderson's successor I do so with pride and pleasure, that a different eye (that of his able and sympathetic successor, Sir Thomas Maclear) fully confirmed Henderson's result with another circle; and further, that Henderson's result has been still further confirmed by additional researches of which I shall presently speak.

I must now pass over briefly the history of succeeding researches, and indeed it has been so admirably and so recently told within these walls by Dr. Ball that it is quite unnecessary I should enter upon it in detail. The most reliable values arrived at for the parallaxes of the stars of the northern hemisphere are given in the following table, and to these results I shall afterwards refer:—

TABLE I.—*Parallaxes of Stars which have been determined in the Northern Heavens with considerable Accuracy*

	Magnitude	Proper motion	Parallax
61 Cygni	6	5·14	0·50
Lalande 21185	7½	4·75	0·50
α Tauri	1	0·19	0·52

Bradley 3077	6	2·09	0·07
85 Pegasi ...	6	1·38	0·05

The recent researches referred to in the title of this evening's lecture are some investigations which, in conjunction with a young American friend, Dr. Elkin, who was my guest for two years, I have recently carried out at the Cape of Good Hope.

The instrument employed was a heliometer—my own property—the good qualities of which I had previously tested at Mauritius in 1874 and at the Island of Ascension in 1877.

Now what is a heliometer? It is a telescope of which the object-glass is divided thus , and the two segments so formed can be moved with respect to each other, thus  and .

Here is a model which has been constructed to illustrate the principle of the instrument. You see that when the two segments are brought into what we may call their natural position, thus , that a heliometer differs in no way from an ordinary telescope—its divided lens produces a single image of a point of light, as will be evident from the image of the single artificial disk now on the screen. In optical language, the optical centres of the two segments are in coincidence, and so the images produced by each segment of the lens are in coincidence. But now, if the segments are separated, either segment produces a separate image of the artificial star, and the separation of the images is proportional to the separation of the segments.

Now, to illustrate how this instrument is used in observation, let there be two artificial stars—*a* and *b*. When the optical centres of the segments are in coincidence, we have on the screen—or in the field of view of the telescope—the images of these two stars. By separating the optical centres of the segments thus  we obtain double images of each of the stars *a* and *b*. Now if we turn the direction of the line of motion of the divided segments parallel to the direction of the stars *a* and *b*, and if we separate the lenses sufficiently we can make one of the images of the star *a* coincide with one of the images of star *b*. Similarly if we cross the segments we can bring the second image of star *b* into coincidence with the second image of star *a*, and if we have finely divided scales attached to the slides by which the segments are separated we can read off, in terms of these scales, the amount of this separation, and this separation is obviously twice the angle between the stars *a b*.

There is now upon the screen a photograph from a drawing illustrating the arrangements by which the segments of my heliometer are moved, and showing the scales by which the amount of the movement is measured; and these scales are read off by a powerful microscope from the eye end of the telescope, as in the photograph of the instrument now on the screen.

There is now on the screen a photograph of a drawing of the most perfect heliometer in the world, recently made by Messrs. Repsold of Hamburg for the Observatory of Yale College, New Haven, U.S. That instrument is now under the charge of my young friend, Dr. Elkin, of whom I have already spoken. If then we wish to observe the angle between two stars, it is only necessary to separate the segments of the object-glass by the required amount, to rotate the tube till the line of section of the object-glass is in the line joining the stars, to direct the axis of the telescope to a point in the heavens midway between the two stars under observation, and then we shall find in the field of view the two stars the angle between which we wish to measure. Then by slow and delicate changes in the distance of the optical centres of the segments, whilst the images of the stars are made to pass and repass through each other—thus—we are able to exactly adjust the angular distance of the segments to correspond truly with angular distance of the stars.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The Museums and Lecture-Rooms Syndicate have recommended the immediate erection of a new lecture-room for physiology, with large additions to the rooms for practical physiology and to the work-rooms adjoining the Comparative Anatomy Museum, at an estimated cost of 7500*l*. These are to be carried along Corn Exchange Street. A work-room for the large class of Elementary Biology is also recommended to be built as an additional story above the Museum of Mineralogy, at a cost of about 2500*l*. It is also recommended that 1000*l*. be laid out in the purchase of microscopes.

The Board of Biology and Geology have modified their report respecting demonstrators and lecturers in Animal Morphology, on learning that the General Board of Studies cannot support their former proposals owing to the financial state of the University. They now ask for a lecturer on Vertebrates at 100*l*. and one on Invertebrates at 50*l*., together with a demonstrator at 150*l*., to be appointed by the Senior Lecturer in Animal Morphology.

The Rev. J. Venn, of Gonville and Caius College, has been approved for the degree of D.Sc.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 15.—"Some Experiments on Metallic Reflection. No. V. On the Amount of Light Reflected by Metallic Surfaces. III." By Sir John Conroy, Bart., M.A. Communicated by Prof. G. G. Stokes, Sec.R.S.

On Silvered Glass Mirrors.—The first set of photometric determinations were made with a silver film deposited on a flat and well-polished glass plate 76·5 mm. long and 51 mm. wide.

The glass plate was weighed before and after being coated with silver, and the weight of the film was found to be 0·0035 grm.; assuming the density of the silver to be 10·62, that being the value for silver finely divided by precipitation given in "Watts's Dictionary," vol. v. p. 277, the thickness of the film calculated from the area and weight was 0·00008447 mm.

The film appeared opaque by ordinary daylight, but when examined with sunlight was seen to be slightly transparent and of a deep blue colour.

The photometrical determinations were made in exactly the same way as those with the speculum metal and steel mirrors (*Proc. Roy. Soc.* vol. xxxvi. p. 187), and the observations were about as concordant as those contained in the Tables I. and II. of the paper giving an account of the experiments.

Two complete series of observations were made with light polarised in, and perpendicularly to, the plane of incidence, and the results are given in Tables I. and II.

The angles of incidence are given in the first column, the percentage amount of light reflected in the second and third, the means of the two sets of observations in the fourth, and the amount of light which ought to have been reflected according to Cauchy's formulæ in the fifth.

TABLE I.—*Silver Film, with Light Polarised in the Plane of Incidence*

Angle of incidence	Observed			Calculated
30	96·74	98·39	97·56	96·66
40	97·06	97·13	97·09	97·01
50	98·35	99·67	99·01	97·45
60	97·06	98·40	97·73	98·02
65	100·0	99·04	99·52	98·29
70	99·02	98·41	98·71	98·61
75	99·02	99·05	99·03	98·94

TABLE II.—*Silver Film, with Light Polarised Perpendicularly to the Plane of Incidence*

Angle of incidence	Observed		C	Mean	Calculated
30	89·25	86·30		87·77	95·74
40	90·69	87·02		88·85	95·30
50	89·31	87·09		88·20	94·66
60	85·10	86·41		85·75	93·75
65	86·09	85·0		85·54	93·22
70	86·33	86·50	83·85	85·56	92·73
75	83·91	87·55	86·17	85·88	92·50

The principal incidences and the principal azimuths were determined, and the means of two sets of eight observations each are given in Table III.

The values of the principal azimuths are higher than any obtained before in the course of these experiments, whilst those of the principal incidences are nearly the same as those obtained with the silver plate polished with rouge (*Proc. Roy. Soc.* vol. xxxi. p. 493), but considerably in excess of the determinations previously made with silver films.

TABLE III.

	Principal incidence		Principal azimuth
	° ′		° ′
	75 38	... ...	44 07
	75 36	... ...	43 40
Mean ...	75 37	... ...	43 53

The calculated and observed values for the light polarised in the plane of incidence agree very fairly, the calculated values being slightly the lowest.

For light polarised perpendicularly to the plane there is considerable difference between the two sets of numbers, the calculated values being considerably the highest.

As has already been stated, the silver film was, to some extent at least, transparent, and it was found that when a Nicol was held between the eye and the silvered glass, and sunlight was incident obliquely upon the film, the brightness and colour of the transmitted light varied with the position of the Nicol; the image of the sun being brightest when the short diagonal of the Nicol was in the plane of incidence, and darkest and of a deep blue colour when the long diagonal was in that plane. Hence it would appear that at oblique incidences light which is polarised perpendicularly to the plane of incidence penetrates to a greater depth in the film than that polarised in the plane—a result that is in accordance with the conclusion drawn from the experiments with silver films already referred to, and one that may account for the difference in the observed and calculated intensities of light polarised perpendicularly to the plane of incidence reflected by the silver film.

In order to ascertain whether the difference between the observed and calculated results was really due to this cause or not, a thicker film was prepared by depositing a second coating of silver on a freshly-prepared film.

The same glass plate was used; the silver weighed 0·0072 grm., and its thickness was therefore 0·0001737 mm., or as nearly as possible double that of the single film.

The thick film was not absolutely opaque, as the disk of the sun on a clear day could just be seen through it, but it transmitted much less light than the film previously used.

Tables IV. and V. give the results of two series of observations made with it, and also the theoretical amount of light which should have been reflected, calculated from the values of the principal incidence and principal azimuth given in Table VI.

TABLE IV.—*Double Silver Film, with Light Polarised in the Plane of Incidence*

Angle of incidence	Observed		Mean	Calculated
30	97·24	97·39	97·31	97·04
40	98·27	98·87	98·57	97·35
50	98·62	101·10	99·86	97·74
60	98·97	99·62	99·29	98·22
65	100·0	99·25	99·62	98·45

75	99·31	99·62	99·44	99·06

TABLE V.—*Double Silver Film, with Light Polarised Perpendicularly to the Plane of Incidence*

Angle of incidence	Observed		Mean	Calculated
30	98·77 100·60	100·40	99·92	96·21
40	97·60	97·50	97·55	95·82
50	98·20	96·28	97·24	95·24
60	97·62	95·67	96·64	94·43
65	95·88	95·68	95·78	93·94
70	94·20	93·11	93·66	93·48
75	94·03	93·77	93·90	93·26

TABLE VI.

	Principal incidence		Principal azimuth
	75 50	... ...	43 52
	75 45	... ...	44 07
Mean ...	75 47	... ...	44

The values of the principal incidence and azimuth are slightly higher than those obtained with the thinner film, and therefore the percentage amount of light which, according to theory, should be reflected by the silver, is also higher.

The tables show that both for light polarised in and perpendicularly to the plane of incidence the observed intensity exceeds the calculated intensity, in the former case by about 1, and in the latter by about 2 per cent., except at incidences of 30° with light polarised in the plane, and 70° and 75° for light polarised perpendicularly to the plane, for which angles the observed and calculated intensities agree closely.

These results appear to confirm the general conclusion arrived at in the former paper, that, although the received formulæ for metallic reflection are approximately correct, they are not a complete expression of the facts of the case.

Zoological Society, May 20.—Sir Joseph Fayrer, F.R.S. vice-president, in the chair.—Mr. W. T. Blanford, F.R.S., exhibited and made remarks on a series of horns of the Wild Sheep of the Pamir, *Ovis polii*, Blyth, which had been obtained by the Hon. Charles A. Ellis, F.Z.S., from the Pamir district during his recent journey to Yarkand.—Mr. R. Bowdler Sharpe exhibited and made remarks on a second specimen of the new European Nuthatch (*Sitta whiteheadi*) recently discovered by Mr. Whitehead in Corsica.—Dr. J. G. Garson exhibited and made remarks upon a specimen of *Lithodes maia*, the Northern Stone-Crab.—Mr. Frank E. Beddard, F.Z.S., read the first of a series of papers on the Isopoda collected during the voyage of H.M.S. *Challenger*. The present communication treated of the genus *Serolis*, sixteen species of which were represented in the specimens obtained during the expedition. Of these nine were described as new. The author also gave a short account of the geographical distribution of the genus, and pointed out some of its peculiar structural points.—Mr. Gwyn Jeffreys, F.R.S., read the eighth part of his papers on the Mollusca of the *Lightning* and *Porcupine* Expeditions. It included the families Aclidæ, Pyramidellidæ, and Eulimidæ, with seventy-five species. Two genera and twenty-three species were described by the author as new to science.—Prof. Jeffrey Bell read the fourth of his series of papers on the Holothurians. The present communication gave an account of the structural characters of the Cotton-Spinner (*Holothuria nigra*), and especially of its Cuvierian organs.—Mr. F. Day read a paper on races and hybrids among the Salmonidæ, in continuation of a former communication made to the Society, and continuing an account of the experiments made by Sir James Gibson-Maitland in the hybridisation of Salmonidæ in the ponds at Howietown.—A communication was read from Mr. R. Collett, C.M.Z.S., containing the description of some apparently new Marsupials obtained by Dr. Limholtz in Northern Queensland. These were described as *Phalangista archeri*, *Ph. herbertensis*, *Ph. lemuroides*, and *Dendrolagus limholtzi*.

Geological Society, May 14.—Prof. T. G. Bonney, F.R.S., president, in the chair.—John Ruscoe was elected a Fellow of the Society.—The following communications were read:—On the pre-Cambrian rocks of Pembrokeshire, with especial reference to the St. David's district, by Dr. Henry Hicks, F.G.S., with an appendix by Thomas Davies, F.G.S. The author in this paper gave further detailed evidence in addition to that already submitted by him, to show that the Geological Survey Map of the district of St. David's and of other parts of Pembrokeshire is incorrect in some of its most essential features, and inaccurate in very many of its petrographical and stratigraphical details. Some new areas in South Pembrokeshire were also referred to. He replied also to the criticisms contained in the paper by the Director-General of the Survey, read last year before the Society, and indicated that Dr. Geikie had completely misunderstood the sections and the order of succession of the rocks at St. David's. He pointed out that the views so elaborately worked out by the Director-General to show the evidence of metamorphism in the rocks, were based on the entirely false supposition that the granitoid rocks were intrusive in the Cambrian rocks, and that the felsites were merely peripheral masses. He showed, by producing abundant fragments of the granitoid rocks and of the felsites from the basal Cambrian conglomerates, that the granitoid rocks were the very oldest rocks in the district, and that they must undoubtedly be of pre-Cambrian age. He proved, from microscopical evidence, that the rocks supposed to have been altered by the intrusion of the granitoid rocks, were in the condition in which they are now found before the Cambrian rocks were deposited, and, moreover, that the supposed concretions in the porcellanites and conglomerates, claimed to have been due to metamorphism, had turned out, on microscopical evidence, to be actually fragments of old pre-Cambrian rhyolites inclosed in the sediments. It was shown also that at the points indicated by the Director-General, where the evidences of intrusion were supposed to be seen, there was not the slightest change of a metamorphic character induced in the sedimentary rocks in contact with the granitoid rocks. The only difference that could possibly be recognised in them by the aid of the microscope was such as is well known to be the result of crushing when in the neighbourhood of faults. Indeed there was the clearest evidence possible to show that the junctions were merely fault junctions. The supposed fold in the Pebidian rocks, the author stated, was impossible if petrological evidence was of any value. The author also produced many facts to show that the conglomerates at the base of the Cambrian constantly overlapped the different members of the series which he claimed to be of pre-Cambrian age, and that the unconformity was very marked and to be clearly seen in many coast sections. The conglomerates were shown also to contain well-rolled pebbles of all the series included under the names Dimetian, Arvonian, and Pebidian, as proved by careful microscopical examination of the fragments by Mr. T. Davies and himself. An appendix by Mr. Davies, describing the microscopic character of the rocks, accompanied the paper.—Note on a specimen of iron amianthus, by the Rev. J. Magens Mello, M.A., F.G.S. The accompanying specimen was found at the bottom of one of the Wingeworth iron-furnaces, near Chesterfield, and was given to the author by Mr. Arthur Carrington, one of the owners. The furnaces have been lately blown out for repairs, and in the mass of slaggy refuse at the bottom a thin layer of the curious product known as iron amianthus was interposed between the sand and the iron refuse. The red sand at the bottom of the furnace was converted in its upper part into a compact, hard, white sandstone an inch or two in thickness, and upon the top of this the iron amianthus occurred in snow-white fibrous masses, the fibres radiating in a concentric manner, and forming more or less botryoidal concretions, somewhat resembling hæmatite in appearance, and separated by extremely thin plates or septa of iron, by which the entire mass is divided into irregular prisms of about half an inch in diameter.

Physical Society, May 24.—New member, Mr. F. C. Phillips, electric engineer.—Prof. W. G. Adams took the chair while the President, Dr. Guthrie, gave a brief summary of his recent researches on eutectic alloys, that is alloys of low fusing point. The complete research will be published in the Society's *Proceedings*. Dr. Guthrie showed by means of tables and curves of results that mixtures of water and nitre, nitre and nitrates, &c., behaved in the same way as fusible alloys, such as alloys of lead and bismuth. On cooling down the alloy or mixture, the ingredient present in richer quantity crystallised out. There seemed to be no definite molecular proportions in these alloys. A "tetra-eutectic" alloy of bismuth 47·38, tin 19·97, lead 19·36, cadmium 13·29 per cent., was exhibited by the author, which fused at 71°, or in boiling alcohol. Rose's fusible metal melts at 93°. Results were given of the behaviour of mixtures of water and the aniline salts, salicylate, oxalate, &c.; also of water and tri-ethylamine, and other members of the ammonia group. Dr. Guthrie's observations tended to show that fusion and solution were of the same nature. He pointed out their bearing on mineralogy and geology, and inferred that water in igneous rocks was there from the first, and not by infiltration, as some suppose.—The President then took the chair, and Dr. W. H. Stone exhibited a simple, cheap, and portable galvanometer for hospital use, made of a boxwood cylinder with coils wound round it, and a needle with mirror, inserted into a test-tube, and pushed into the hollow of the cylinder. The needle is made dead-beat by putting paraffin oil into the tube. He also exhibited a Kohlrausch metre bridge for alternating currents, a telephone playing the part of indicator. Dr. Stone employs it for measuring the resistance of the human body, which he finds to be less than 1000 ohms. With high-tension currents it appears lower than with low-tension currents. Another metre bridge of the kind with a longer wire (3 m. in this case as compared with ½ m. in the other) was also shown in connection with a sledge induction-coil, by which the power of the current can be regulated to suit the patient. Dr. Stone stated that the body acts more like a solid than a liquid conductor. Mr. Glazebrook said he had used a similar plan with a telephone to measure the resistance of electrolytes; but found the telephone too sensitive from induction, though in Dr. Stone's work this objection might not apply. Prof. G. Forbes stated that the telephone had been applied in a similar way to comparing capacities. With regard to the danger from currents, Prof. Ayrton said the E.M.F. of the railway current at Bushmills was 250 volts, and pointed out that very intermittent currents

were more dangerous than fairly continuous ones. Dr. Stone thought that with good skin contact (as with salt and water) this E.M.F. would be dangerous. Mr. Lecky instanced the reported death of a horse at Bushmills by a shock.—A new speed indicator, especially for marine engines, was exhibited by Mr. W. T. Goolden and Sir A. Campbell of Blythswood. Its action depended on the rolling of a disk on a cone, the disk traversing a screw driven by the engine-shaft. The disk forms the nut of the screw, and rotates in an opposite direction to the latter. Its position on the screw depends on the surface velocity of the cone, which is kept turning at a uniform rate by clockwork. In travelling, the disk makes a series of electric currents which indicate its position on a set of dials detached. Recording apparatus can be added. The apparatus was made by Mr. A. Hilger.—Mr. W. Baily exhibited a similar device, in which the cone was replaced by a circular plane or disk. He had invented this independently, and it had the advantage of giving a zero position to the rolling disk, though the cone was the more compact arrangement. The idea of using a screw in this manner was suggested by Mr. Shaw of Bristol some three years ago.

BERLIN

Physiological Society, May 2.—Dr. Bender gave a short description of a preparation which he exhibited at the end of the meeting. It was an axolotl in the stage of development in which the heart consists of a tube with a sacular expansion at one part, corresponding to the atrium, and then forms a loop, the ventricle, afterwards passing over into a second expansion, the bulb; the animal is in this stage still transparent enough to permit of the movement of the blood through the three chambers of the heart being seen distinctly.—Dr. Herter described the experiments which Dr. Lukjanow had made in his laboratory upon the influence of increased tension upon the absorption of oxygen. The question is of physiological importance because, if it is decided by experiment in the negative, the existence of an optimum amount of oxygen in the air will be proved, which would coincide with normal percentage proportion of oxygen in the air, whereas if the experiment should result in proving that the absorption of oxygen increases with the increase of the oxygen tension, then this oxygen absorption and the consequent oxidations would have to be included in the general combustion processes whose intensity is known to increase with the increased tension of oxygen. The experiments were conducted after the method of Regnault and Reiset. The animals were placed inside a bell-jar, into which the air entered on one side along with an additional quantity of oxygen, which could be varied at pleasure, and from which it was drawn off on the opposite side by a tube which passed into the absorption vessels where the carbonic acid was removed, and the residue was provided with fresh oxygen and led back into the bell-jar. An offset from the air tube allowed of a sample of the expired air being drawn off at any time for analysis. In all fifty animals were experimented upon, which were kept fasting for half a day before commencing the experiment. The oxygen of the inspired air varied between 30 and 90 per cent. The mean result of all the experiments on guinea-pigs, rats, dogs, and cats, was a slight increase of the oxygen absorption, to wit 104 volumes as against 100 absorbed from normal air. Dr. Herter is of opinion that this small increase cannot be regarded as a consequence of the increased oxygen tension, because, in individual animals, the means of oxygen absorption sometimes fell below, and sometimes exceeded the normal amounts, and further, because they did not vary proportionally with the increased tension of oxygen in the air. The small increase of the general mean must be referred to other causes, *i.e.* the movements of the animals during the experiments. No increase of temperature was observed under the increased pressure of oxygen. Further experiments were made upon animals in which one could assume an increased demand for oxygen in consequence of high fever being present, but not even did the animals that had fever take up more oxygen from the air that was charged with a more than normal amount of oxygen. Likewise, animals from whom a large quantity of blood had been withdrawn behaved in exactly the same way as normal animals in presence of the surplus of oxygen. The conclusion to be drawn from all these experiments is that the absorption of oxygen is not an ordinary combustion process, and that the normal composition of the atmosphere contains an optimum percentage amount of oxygen.—Prof. Busch spoke about caries of the teeth which has been so little scientifically investigated, because in studying it the external hurtful processes have been alone considered, whereas the second important factor, the resisting power of the teeth, has been quite overlooked. In regard to the latter, Prof. Busch called attention to the fact that caries of the teeth had been observed in no animal, and that it appeared to be peculiar to man. Caries of the teeth, however, appears not to be a characteristic of civilised man alone, but it has been observed in large collections of skulls even in those of prehistoric time. Some races are more disposed to it than others. For instance, the Celtic, Arabian, and Polish races appear to possess a relative immunity. This is less the case with the Indo-Germanic race. Certain families are particularly predisposed to it. General habit of body has a pronounced influence upon its development, as well as menstruation and pregnancy in women, chlorosis, typhoid, &c. Disposition to caries shows itself even in the developing tooth in the composition of its enamel, which is undulating, whereas teeth with quite smooth enamel have much greater power of resistance. The enamel appears to be the only tissue in the body which is subject to no metabolism, and which remains quite unchanged. Every alteration in it which is caused by external influences, and every defect of the enamel remains during the whole of life, and can never be repaired. Dentine also shows differences in its structure as regards its disposition to caries. The dentine tubes either run regularly close side by side to each other, such teeth having a greater power of resistance; or the dentine tubes branch and surround cellular bodies, or even small air vesicles, such teeth falling an easy prey to caries. If dentine has been decalcified at any place by the action of acids, it undergoes putrefaction under the influence of bacteria which do not seem to belong to any specific species. Dentine is sensitive, although nerve filaments have not as yet been traced into it. Actual toothache does not occur in the course of caries until it has reached the pulp. The inflammation of the pulp is particularly violent and painful, because the tissue is so richly supplied with blood-vessels and nerve-filaments. As the products of inflammation cannot escape, they collect and work their way downwards, where they produce the most painful inflammation of the roots and the periosteum. The chief object of the rational treatment of caries of the teeth consists in the removal of every particle of carious substance out of the diseased tooth and to protect the sound dentine that has been exposed against external injurious influences by covering it with a firm substance which is not attacked by acids: gutta-percha, cement, or gold. Although the dentine is not as unchangeable as the enamel, but manifests, by its becoming firmer or softer, that it is not quite uninfluenced by tissue changes, yet its caries is not an irritative process that the dentine takes an active part in, but a passive process, and consequently the removal of all diseased portions, and the protection of the non-carious part of the tooth by filling with a resistant mass suffices to stay the morbid process completely.

BRITISH MITES

The British Oribatidæ. By A. D. Michael. (Ray Society, 1884.)

WE congratulate the Ray Society on this valuable addition to their excellent series of monographs. Mr. Michael indeed modestly asks us to "kindly remember that this book is the record of work done in the scanty leisure of a very busy man," but though this may add to our gratitude, and serve as an encouragement to others, no one, we think, after reading the book will feel that any excuse or apology was needed. When Mr. Michael commenced his study of this curious family of mites scarcely any species were recorded as British, there were very few of which the whole life-history was known, and Nicolet's was the only work dealing with the anatomy of the family.

Mites are not perhaps a very attractive group, nevertheless many species are extremely curious and some very pretty, as a glance at Mr. Michael's excellent figures is sufficient to show, especially those of *Tegeocranus latus*, *Leiosoma palmicinctum*, and *Cepheus ocellatus;* possibly indeed, says Mr. Michael, "no more bizarre or remarkable creatures exist than these, when nearly fully grown, and bearing on their backs, ring within ring, concentric circles or ovals of these curious and disproportionately large line-of-beauty shaped spines formed of clear, colourless chitin, and strongly serrated in the first species, and of the beautiful and iridescent membranous fans in the two latter."

Some, he adds, especially "of the immature stages are amongst the most beautiful creatures of the order; and only those who are not acquainted with the Acarina can suppose that none are beautiful. It is needless to say that the Oribatidæ are highly interesting and instructive, because the same thing may be said of every family of created beings; no one can devote himself to the study of any class of organism without becoming from day to day more deeply impressed with the admirable manner in which its members are adapted to their wants, and the marvellous way in which the different parts are varied in different species, so as to provide more efficiently for their protection and continuance. This fact of having constantly before his eyes the wonders of the individual family or order which he is investigating is apt to cause the specialist to forget for the time that there are hundreds of other families equally interesting, beautiful, and wonderful in their construction and life-histories. It is only by endeavouring to base his special knowledge upon the wider foundation of general interest in the works of nature that the naturalist escapes this error, and appreciates the harmony between the particular class and other equally glorious types of life. Endeavouring to bear all this in mind, I feel that I am not justified in saying that the Oribatidæ have any claim on the biologist beyond that of any of the endless varieties of other forms of animals; but I do say that they have an equal claim; and I think I may confidently assert that any observer who inquires into the complex structure of these minute creatures, their singular life-histories, or the quaint and somewhat exceptional habits of some of the species, will rise from his task fully rewarded for the time that he has spent."

The work is divided into two parts: in the first the author gives an account of the terminology, literature, classification, development, habits, methods of collection and preparation, and anatomy; while the second is devoted to descriptions of the genera and species.

The principal home of the Oribatidæ is in moss of various sorts, on lichens, and in fungi; others live in dead wood, many are found in the debris under furze bushes, in the needles of which the nymphs burrow. Pelops, Hoplophora, and others are found among the fallen leaves of Scotch pines; some frequent other trees, while *Oribata sphagni* and *Notaspis lacustris* are aquatic. The whole family with one doubtful exception are vegetable feeders; and, being without any weapons of offence, are all the more in need of defensive arrangements, with which indeed they are liberally provided. Their carapace is thick, with in many cases curious provisions for the protection of the legs, and they most of them have the habit of shamming dead.

Mr. Michael differs from the account given by Nicolet of the internal anatomy in several important respects, and considers that the conspicuous organs, usually called stigmata, are really organs of sense, probably of hearing or smell, and he says, "I incline to the former."

The life-history falls into four well-marked periods—the egg, larva, nymph, and imago. Dujardin indeed asserted that the Oribatidæ are viviparous, and the statement has been repeated in various standard books, but as a general rule the reverse is the case. The egg is generally elliptical, or cylindrical with rounded ends. In some cases it absorbs moisture, and the exterior membrane, being hard and brittle, splits longitudinally and allows the inner or vitelline membrane to be seen through the opening. This constitutes the stage called by Claparède the "Deutovum."

The larva is invariably hexapod, and all six legs are monodactyle, tridactyle tarsi being confined to the imagos. The larval stage is comparatively short, generally lasting from three weeks to two or three months. Mr. Michael does not consider that the larva undergoes any change of skin until it passes into the nymph.

The nymph "may be defined as the creature after it has become octopod," but before the first month. It is the principal period of growth and occupies a considerable proportion of the lifetime; "it is also the time of gay colouring and of beauty." "When the nymph is fully fed, and is about to become an imago, it creeps into a hole, or some other sheltered position, stretches out its legs, fixing its large monodactyle claws firmly into the substance it is resting on, and then gradually becomes inert, perfectly motionless, and to all appearance dead; it ceases to feed, and does not exhibit any sign of life if touched or injured."

Mr. Michael coincides with the opinion of Claparède and Mégnin that during this period there is an entire reorganisation of the internal structures, and "the different parts of the body of the adult are formed, not at the expense of the same parts of the nymphs, but from the general body substance."

Till Mr. Michael traced the life-histories of these creatures, the immature stages of eight species only were known to us. Nicolet, indeed, gives eleven, but as to three he is, in Mr. Michael's opinion, certainly in error. In all other species the life-history when known has been traced by Mr. Michael himself.

In breeding Mr. Michael used glass cells "composed of ordinary microscopical glass slips 3×1 inch, having in the centre, fastened by marine glue or Canada balsam, a glass ring made of a transverse slice of glass tubing about $\frac{3}{4}$ or $\frac{7}{8}$ inch in diameter, the length of the tube, and consequently the depth of the cells, being usually about $\frac{3}{8}$ inch. The tubing I employ is of tolerably thin glass, if very thick it is opaque, and leaves little room inside the cell. Over this a thin glass cover, rather larger than the diameter of the tubing, was laid, either a circle or a square; the latter is often handy, as the projecting corners are convenient to take it on or off by, or sometimes a second slide or a broken piece of one is more serviceable. This cover was always quite loose, and simply held on by an ordinary brass-wire microscopical spring-clip; of course the upper edge of the slice of glass tube required to be smooth, so that the cover would lie flat upon it, and not allow the minute prisoners to escape. A cell so prepared was carefully cleaned out, and examined under the microscope, to see that it did not contain Acarina or ova. A small piece of thick white blotting-paper, not large enough to cover the whole bottom of the cell, was then placed in it and damped; a piece or two of growing moss or fungus was then placed in the cell, having first been carefully examined under the microscope to see that it also was free from Acarina and ova, and the cell was then ready for use. One or two specimens of the larva, nymph, or species to be observed, were placed in the cell, never so many but what I knew each individual specimen; the cover was put on, fixed with the clip; a label with a statement of what was inside affixed to the slip, and the whole put away in the dark or very dull light."

Another good mode of providing the fungus-eating species with food Mr. Michael found to be by putting a minute piece of mouldy cheese in the cell; this soon bore a fine crop, which was highly appreciated. He found these simple cells answer better than any more elaborate apparatus. Mr. Macintyre's ingenious cork cells, so useful for many small insects, are not suitable for Oribatidæ, in the first place because many are wood-borers, and even those which are not often get lost in the interspaces of the cork. He also found that these cells got dry more rapidly.

He tells us indeed (and having had some experience in similar observations I doubt not that it is so) that no portion of his work has been either more laborious or more interesting than that of tracing the life-histories of the different species through their immature stages. The creatures are minute, scarcely visible indeed to the naked eye, they avoid the light and always endeavour to hide themselves, and yet they must be frequently examined to see what is going on. They must not be touched with any hard instrument, and lastly their transformations last for many months, sometimes for more than a year.

It is obvious indeed that his observations required great and constant care. The hygrometric condition of the cell required continued watching, since if it were made too damp or allowed to get too dry, even for an hour, the labour of months would be lost. Mr. Michael carried his mites about with him on any journey, but it is obvious that alone he would have been wholly unable to devote sufficient time to the care of them, and it was, he tells us, mainly to his wife's patient attention and skilled fingers that his success in rearing them was due. To Mrs. Michael then, as well as to her husband, we will tender our warm thanks and congratulations on this excellent contribution to the natural history of the British Isles.

JOHN LUBBOCK

INJURIOUS INSECTS

Reports of Observations of Injurious Insects and Common Crop Pests during the Year 1883; *with Methods of Preservation and Remedy.* By Eleanor A. Ormerod, F.R.Met.Soc., &c. Pp. 1-80 and 1-16. (London: Simpkin, Marshall, and Co., 1884.)

WE have to congratulate Miss Ormerod on having again produced an excellent summary of the evil doings of injurious insects in this country during the past year. It is full of interesting and useful information, from personal observation, and from the reports sent in by the staff of assistants she has enlisted into her service. Regarded from a popular point of view these annual Reports do great service by explaining to those interested the real nature of their insect foes; from a scientific point of view they may do good service by stimulating inquiry, and occasionally bringing to light the hitherto unknown life-histories of certain species; and they should do paramount service from an economical point of view. This latter is really the most important of all, and the item of *expense* in application of remedies is always a serious consideration. With some crops it may sometimes be doubtful if the outlay would be sufficiently recouped; with others (hops for example) the case different. In that year of hop-famine, 1882, we heard of one grower who expended 15*l.* an acre on washing, and was amply and abundantly repaid, but if all had done the same his profit would have been much less, though the general advantage would have been much greater: possibly in his case his gardens were comparatively isolated, and not subject to migrations from those of less careful neighbours. While on this point we observe that Miss Ormerod is inclined to believe in the supposed migration of the hop-aphis from plum to hop. The habit of migration in *Aphides* from one plant to another totally different is most strongly asserted by Lichtenstein, and almost as strongly pooh-poohed by others. At present we incline to the side of the observant French *savant*, because he states results from actual observation and experiment, whereas his opponents simply deny the possibility.

On one point we do not think Miss Ormerod has proved her case. She inclines to the belief that Myriopods ("False wire-worms" as she terms them) *are* "pests," and do devour healthy vegetable growth; nothing is impossible, but more proof than that given will be required in order to convince those who hold a contrary opinion.

That much vexed sparrow question is touched upon, not in a manner favourable to the sparrow. It is really a vexed question, and we fear will remain so. In the

writer's garden the sparrows are at this moment doing their best to clear the rose-trees of the "green-fly" that infest them, and there can be no doubt that at this season the sparrow is almost entirely insectivorous; at other seasons it is almost equally granivorous; possibly a judicious thinning of sparrows may be salutary, but those who advocate wholesale slaughter should bear in mind the results of the indiscriminate destruction of raptorial birds in these islands.

Miss Ormerod is not always happy in her nomenclature. Excepting in one book there is no such thing known as "*Hybernia prosapiaria*" (p. 5), the specific appellation rightly belonging to an entirely different insect; moreover had she consulted any recent work or list on *Micro-Lepidoptera* she would not have penned the footnote that appears at p. 67.

The illustrations (even if most of them be old and familiar) are good, and add to the usefulness of the Report.

In future Reports we think it deserves Miss Ormerod's consideration whether a meteorological summary in tabular form would not prove a useful addition, compiled especially with regard to the comparative abundance or scarcity of particular injurious species in former years, in connection with the temperature and rainfall in every month of each year.

R. McL.

OUR BOOK SHELF

An Elementary Treatise on the Integral Calculus, containing Applications to Plane Curves and Surfaces; with Numerous Examples. By B. Williamson, F.R.S. (London: Longmans, 1884.)

A WORK by Mr. Williamson is like good wine, and needs no commendation from us. We note that this has reached a fourth edition, but Mr. Williamson does not rest content with what he has already achieved. He has given a touch here, brought out into greater prominence a feature there, and not only so, but he has at last added a new detail in the shape of a chapter on multiple integration. In our notices of former editions we have drawn attention to the absence of such a chapter, and we are glad to see that he has at last introduced what he hopes "will be found a useful addition to the book." We need only remark further that this edition has 393 pages against 375 pages in the third edition.

An Elementary Treatise on Solid Geometry. By Charles Smith, M.A. (London: Macmillan and Co., 1884.)

MR. SMITH has already won his spurs as a mathematical writer by his admirable "Conics." This work, as far as possible, is on the same lines. It is not intended to supersede the classic treatises by Salmon and Frost any more than his former book was to take the place of the splendid work on "Conics" by the former of the above-named writers. A feature in Mr. Smith's treatment of the subject is the early discussion of the different surfaces which can be represented by the general equation of the second degree; and in the way in which these surfaces are here handled we think the student will be much interested. The discussion is full and very clear. An excellent collection of exercises adds much to the value of the book for students: those in the body of the chapters being well fitted to bring the text home to the reader. For the majority of students we should say, "Read Smith's 'Solid Geometry,' and you will not need any other work." Those who wish to penetrate into the inmost recesses will find that they have been helped by the study of this work to attack the masterpieces referred to at the outset of our notice.

A Collection of Examples on the Analytic Geometry of Plane Conics; to which are added some Examples on Sphero-Conics. By R. A. Roberts, M.A. (Dublin University Press Series, 1884.)

WE had the pleasure of noticing with commendation (NATURE, vol. xxvi. p. 197) a previous collection of examples by Mr. Roberts on conics and some of the higher plane curves. This has all the merits of the former work, with, we fancy, increased power and skill in the methods employed. A portion of the exercises is common to both works. Much space is devoted to the discussion of properties of circles connected with a conic, especially of circles having double contact with the curve. Great use is here made, and effectively, of elliptic coordinates. "This method simplifies greatly the study of relations involving the angles of intersection of such systems," *i.e.* as have double contact with two fixed confocal conics, "whose differential equations take a simple form." In all there are fifteen chapters, the last of which treats of sphero-conics; in this chapter also much use is made of elliptic coordinates. The collection is likely to be very serviceable to junior students, and will be convenient for reference generally. After perusal we have not detected, we believe, any errata that will cause such students as can use the book with profit any trouble.

Mineralogy. Vol. II. Systematic and Descriptive. By J. H. Collins, F.G.S. (Collins's Advanced Science Series.) (London and Glasgow: W. Collins, Sons, and Co., 1883.)

THIS little book is not, neither does it profess to be, more than a dictionary of minerals. The names, localities, and general characters are given as briefly as possible; and the work seems to be brought up to latest date.

The only point in which the author lays claim to originality of treatment is the classification, and it is precisely here that exception may be taken to the book, with its system of Pyritoids, Spathoids, Haloids, Plethoids, Brithoids, &c., and partial neglect of isomorphous groups. Cerussite, for example, is grouped with phosgenite instead of with aragonite, witherite, &c.

There are a number of crystal figures, but the notations, where used, are not consistent; and in one case, where the cleavages of barytes are wrongly described, the notation is meaningless.

There are several typographical and other errors which should be corrected in a second edition—*e.g.* "Senaviza" (p. 61) should be "Serravezza"; feather-ore (p. 60) should be referred to jamesonite, and not to berthierite; "eulitite" (p. 239) should be "eulytite."

It can scarcely be expected that the book will be much used by the "practical miners, quarrymen, and field-geologists" for whom it is intended. The other readers for whom the author writes, "students of the science classes," may however find it a useful and compendious book of reference, as containing a very complete list of minerals.

Handbook of Vertebrate Dissection. Part III. "How to Dissect a Rodent." By H. Newell Martin, D.Sc., M.D., M.A., and William A. Moale, M.D. (New York: Macmillan and Co., 1884.)

IN the third of their series of Handbooks of Vertebrate Dissection, Drs. Martin and Moale describe a mammal, taking as a type the common rat.

In spite of the authors' remark in the preface that "he who aspires to become a comparative anatomist, and yet finds a rat too small for the observation of all the main facts in its structure, has mistaken his vocation," we think that, for beginners, a larger mammal would have been preferable—at any rate for those who do not aspire to

measurement of the resistance of the human body, suggested that the latter instrument was too sensitive, and that from self-induction perfect silence could not be obtained. Both these remarks are true; but if time and the chairman had permitted, I should have said that absolute silence is rarely got, but that the minimum of sound is so easy, after a little practice, to estimate, that one-hundredth of a revolution on either side of it is instantly detected. The bridge wire takes ten turns on the barrel; consequently this amount is the thousandth part of a wire three metres long. Using a fixed resistance of 100ω, the possible error is quite unimportant, and even with 1000ω it is far within other instrumental accidents.

But as in the somewhat similar case of counting "beats" between tuning-forks, a sensitive and an educated ear is needed. At first starting I found that I made considerable mistakes, one of which is recorded in a paper contributed to NATURE some weeks back. W. H. STONE

Wandsworth

Simple Methods of Measuring the Transpiration of Plants

THE "potétomètre" described in NATURE, May 22, p. 79, appears to be an ingenious but a rather complicated instrument. Experience has, however, taught me that the extremest simplicity is most desirable. Mr. Ward hints at difficulties of manipulation which are quite conceivable. The plan I have adopted, and find to answer, as far as it goes, is to insert the cut end in a small test-tube and cover the surface of the water with a little oil. The whole can then be weighed to three places of decimals, and the absolute amount of loss in a given time is easily ascertainable.

But a serious objection must be made against all experiments with cut shoots and leaves, for they can only give, at best, unsatisfactory results. The amount of transpiration varies so much under the ever-changing conditions of light, heat, dryness, &c., that it is only by a long series of comparative experiments *with the same specimen* that the differences peculiar to each kind of plant can be ascertained; and no cut shoot can be employed for two or three days, much less for several days, as are necessary for obtaining satisfactory results; as the amount of loss steadily decreases till death ensues, although the shoot may be *apparently* quite healthy for a long time. I have been experimenting for several summers on the transpiration of plants under coloured lights, and at first used cut specimens, as so many experimenters have done, but I found they were most untrustworthy. I now grow the plants in miniature pots, which are covered up in gutta-percha sheeting. These can be weighed to two places of decimals. By this simple method all difficulties are entirely obviated. Drayton House, Ealing

Worm-eating Larva

THE following note, which I received from the Rev. Robt. Dunn of Cricklade, may be worth publishing in reference to Prof. McKenny Hughes's "Notes on Earthworms." Mr. Dunn says: "This afternoon (May 6) on a gravel path I saw a worm wriggling in an unusual way, and stooping down I saw that a big earthworm had a smaller worm hanging on at the belt or knob, or whatever you call it; so I got a bit of stick and pushed off the parasite and found it no worm, but I should say a sort of centipede, with a very red head, about one inch long. So I captured him and put him in methylated spirit, when he vomited what I presume was worm's blood." He further adds that what the beast vomited was a stream of crimson fluid; it separated at once into white flocculent matter with brick-red specks, but since it has all turned into a white sediment. Mr. Dunn sent me the animal, which proves to be the larva of a beetle, either one of the Staphylinidæ or Geodephaga.[1]

Cultivation of Salmon Rivers

I HOPE we may assume, from the paragraph which appears among the "Notes" in your issue of last Thursday (p. 129), that the Fishery Board for Scotland is about to take some active course towards the removal of obstructions to the ascent of salmon up Scottish rivers. When you say the Board "is specially desirous to introduce as soon as possible a fishway at the falls, and this, when done, would open up some 500 miles of excellent fishing and spawning ground," I hardly think you can be alluding to any one particular river. Am I correct in supposing you refer to the aggregate mileage of rivers in Scotland now closed by *natural* obstructions, *i.e.* waterfalls? The Report of the Special Commission to inquire into the condition of the salmon fisheries of Scotland, published in 1871, informed us that the River Tay alone had some 115 miles of river blocked against the salmon by the two natural obstructions of the Tummel Falls and the Falls of Garry on the two important Tay tributaries from which the respective waterfalls are named. If your "Note" meant to include the entire mileage of Scottish rivers seriously affected by artificial dams of a more or less obstructive character (and their name is legion in Scotland), as well as by the natural barriers that occur, I think 500 miles of obstructed fishing and spawning ground is far too low an estimate; it might in fact, I should say, be multiplied at the very least by three. Now that theoretical playthings are being laid aside, and in their place appears a prospect of a more sound, natural, and scientific basis being made the foundation of our future salmon cultivation, the absolute necessity of opening up the natural breeding-beds of the fish will, it is hoped, become patent to every one, and the dream of my old friend the late William J. Ffennel, the father, so to speak, of our modern salmon fishery legislation and salmon river cultivation may at last be realised. "If I live," he said to me one day (I hardly care to remember how long ago it was, or how soon after he was taken from us), "I shall never rest until every weir and mill-dam in the three countries—England, Ireland, and Scotland—has a thoroughly good and permanent salmon ladder built upon it, or into it, or around it. We have shown we can restore the fisheries; we must now restore the rivers. That, sir, is the true position to take up, and that must be our next aim." Had Mr. Ffennel lived, river restoration would probably have progressed more than it has during the last decade. MARK HERON

[The falls referred to in our note on the Fishery Board for Scotland last week (p. 129) are the Falls of the Tummel.—ED.

A RARE BRITISH HOLOTHURIAN

OF the six species of Holothurians with shield-shaped tentacles (the Aspidochirotæ) that are known to occur on the shores of the North Atlantic Ocean, two—*H. obscura* and *H. agglutinata*—were so shortly described by Le Sueur as to be still strange to American naturalists; no definite statement as to the presence of a true, that is, aspidochirote, Holothurian in the British seas has ever made its way into any systematic revision or synopsis of the class.

Shortly, however, after the publication of Forbes' "British Starfishes," Mr. Peach of Gorran Haven, Cornwall, published in the *Annals and Magazine of Natural History* for 1845 (vol. xv. p. 171) a short article on the "Nigger" or "Cotton-Spinner" of the Cornish fishermen, in which he quite rightly remarks that no typical Holothurian with twenty tentacles had been observed by Forbes, and exhibits a just pleasure in being able to say that he had discovered one. Later, two Irish naturalists—Prof. Kinahan and Mr. Foot—separately noted the existence of what one called *Cucumaria niger* and the other *Holothuria niger*. With an exception to be mentioned immediately, no writer has for nearly forty years given the least indication of a knowledge of the existence of this "Cotton-Spinner," and it may therefore be supposed that it was always with interest that I examined any form that came from the British seas. A short time since, on opening a Holothurian that had been in the British Museum for nearly twenty years, I found that, instead of those tubules which, arising from the wall of the cloaca, were first seen by Cuvier, and called Cuvierian organs by Johannes Müller, being small and inconspicuous, or, as often happens, altogether absent, they formed rather a large, almost solid, compact mass of

[1] Mr. W. F. Blandford has called my attention to an account of a similar encounter between a worm and a larva given in Dallas's "Elements of Entomology," p. 6.

closely-packed tubes, which overlay the rectal portion of the intestine, and occupied nearly one-third of the general body-cavity.

On comparing the general structure of this animal with the account given by Mr. Peach, I found that his article dealt so little with anatomical points that it was impossible to say whether or no there was any real relation between his "Cotton-Spinner" and my specimens, which, like his, were of Cornish origin. There was, however, a physiological experiment that could be made, and which might, I hoped, be successful. In the description given by our modern master of Holothurian organisation, Semper says, in speaking of the Cuvierian organs: "The sticky property of these organs is known in the true Holothurians, and in England they have even given the name of the 'Cotton-Spinner' to *Holothuria nigra*." I attempted to draw out one of the tubes of the mass, and, as I hoped, I found it extend. I threw it into water, and I found that it swelled out. More accurate experiment showed that it could be made to elongate twelve times and to swell out in water to seven times its diameter. It was at once clear that I had before me the creature of whom Peach had written: "It is extremely irritable, and, on being touched or disturbed, throws out a bunch of white tapered threads about an inch in length and one-eighth in thickness." Peach goes on to say that they "soon become attenuated, either by the agitation of the water or the coming into contact with something;" but as he goes on to say that they stick to everything they touch, I doubt not that, when that thing is alive it tries to run away, till the moral effect of the gradually elongating and as regularly swelling threads paralyses it with fear. At Dr. Günther's suggestion I tested the strength of these elongated threads, and I found that, when so thin as to be barely visible, six were strong enough to hold up a weight of between 800 and 1000 grains.

I communicated a paper detailing the zoological and anatomical characters of this very rare form, which seems to be known only to the fishermen of Cornwall, to the Zoological Society at their meeting on May 20, and I direct attention to it in this more widely circulated journal because it seems to show in a very pointed way how from the absence of opportunity for investigating animals that live not deeper than twenty fathoms we do not only remain ignorant of the contents of our own seas, but that we have in this "Cotton-Spinner" an opportunity of testing the hypothesis of Semper as to the function of these Cuvierian organs, and of putting on the basis of scientific observation and experiment the "great detestation" in which, as Peach tells us, they are held by the fishermen. While Cuvier regarded the organs to which in later years he was made name-father as testes, and Jäger and the great majority of subsequent writers as kidneys, Semper, who had unexampled opportunities of watching and examining them in the Philippines, came to the conclusion that they were organs of offence or defence. To this conclusion the French naturalist Jourdan and the German Dr. Hamann have been led on the ground of histological observation; in England the only observations yet made have been such as are possible in a museum with specimens that have been in spirit for nearly twenty years. I earnestly hope that the line of investigation indicated by the facts that are here recorded will be soon followed out by one who is working in a marine biological laboratory on the British coast.

F. JEFFREY BELL

VISITATION OF THE ROYAL OBSERVATORY

THE visitation of the Royal Observatory, Greenwich, took place on Saturday last, when there was a very numerous attendance of astronomers and representatives of the allied sciences. The Report this year does not contain anything striking, but enables us to see how usefully and smoothly the work of the Observatory has been going on during the past year. Still novelties were not entirely absent, chief among them being the new Lassell reflector.

The new dome for this telescope was completed by Messrs. T. Cooke and Sons at the end of last March, and is in every respect satisfactory. It is thirty feet in diameter, covered with *papier-mâché*, on an iron framework, and turns with great ease. The shutter-opening extends from beyond the zenith to the horizon and is closed by a single curved shutter (3 feet 6 inches wide at the zenith and 6 feet wide at the horizon), which turns about a point in the dome-curb opposite to the shutter-opening, and runs on guiding-rails at the horizon and near the zenith, the curved shutter being continued by an open framework to complete the semicircle. This arrangement appears to leave nothing to be desired as regards ease of manipulation. After the completion of the dome, the carpenters' work on the flooring, &c., of the building and the attachment of the observing-stage (which is fixed to the dome) have necessarily occupied much time, and the building is hardly yet complete in all details. The equatorial has required a number of small repairs and general cleaning, some parts of the mounting having been probably strained in process of removal, and the bearings in particular having suffered from wear and subsequent disuse, so that it has been necessary to raise the instrument and regrind these in several instances. The mirror has been cleaned, and appears to be in very good condition as regards polish. The definition on stars seems to be very good as far as it has been practicable to test it before the mounting of the telescope has been put into proper order. The delay in the completion of the dome has necessarily delayed the work on the instrument, which is now rapidly advancing to completion.

First among the astronomical observations properly so called referred to by the Astronomer-Royal was the work done by the transit-circle. "There is no change of importance to notice in this instrument, which has been kept in good working order. A reversion-prism for use with the collimators as well as with the transit-circle is being made by Messrs. Troughton and Simms. The sun, moon, planets, and fundamental stars have been regularly observed throughout the year, together with other stars from a working catalogue of 2600 stars, comprising all stars down to the sixth magnitude inclusive which have not been observed since 1860. Considerable progress has been made in obtaining the requisite three observations of each star, and there is a good prospect that by the end of next year, when it is proposed to form a new Nine-Year Catalogue, the whole of the stars will be cleared off. The annual catalogue of stars observed in 1883 contains about 1550 stars."

The following statement shows the number of observations with the transit-circle made in the year ending 1884 May 20:—

Transits, the separate limbs being counted as separate observations	5213
Determinations of collimation error	303
Determinations of level error	360
Circle observations	5049
Determinations of nadir point (included in the number of circle-observations)	353
Reflection-observations of stars (similarly included)	548

As regards the computations—

Clock times of transit over the true meridian, corrected for collimation, level and azimuth errors, are prepared to	1884 May 18
Clock errors and rates are determined to	May 11
Mean R.A.'s for 1884 January 1 are prepared to	May 11

In connection with this class of observation it is interesting to remark that the mean error of the moon's tabular place deduced from the meridian observations of 1883 has been brought down to + 0·03s. in right ascension and + 0″·42 in longitude. This result has arisen because in this year Prof. Newcomb's corrections to Hansen's tables have been applied in the *Nautical Almanac*, so that the comparison has reference to Hansen's theory without his empirical term of long period (intended to represent the direct action of Venus) and with an empirical alteration in the epoch of the inequality resulting from the indirect action of Venus. The mean error of Hansen's tables uncorrected was + 0·82s. in R.A. for the year 1882.

The most important reference to the spectroscopic work is the following:—

"For the determination of motions of stars in the line of sight, 412 measures have been made of the displacement of the F line in the spectra of 48 stars, 91 measures of the *b* lines in 19 stars, and two measures of the D lines in one star, besides measures of the displacements of the *b* and F lines in the spectra of the east and west limbs of Jupiter, and in the spectra of Venus and Mars, and comparisons with lines in the moon or sky spectrum made in the course of every night's observations of star-motions, or on the following morning, as a check on the adjustment of the spectroscope. Some preliminary measures have also been made of the F line in the spectrum of the Orion Nebula. The progressive change in the motion of Sirius, from recession to approach, alluded to in the last two Reports, is fully confirmed by numerous observations since last autumn, and a change of the same character is indicated in the case of Procyon. A discussion of the measures of all the stars observed here, on which I am now engaged, shows that the results of the four periods—1875 June to 1877 May, 1877 June to 1880 December, 1881 January to 1882 March 10, 1882 March 11 to 1884 March 31, in each of which the instrumental conditions were different—accord generally within the limits of the probable errors, and that there is no systematic change from recession to approach, so that the presumption against error arising from defective instrumental adjustment appears to be strong."

Passing on to another branch of the work at present undertaken by the Observatory, that connected with photographs of the sun with the view to determine the amount of spotted area, &c., we learn that two important changes have been made. First, the heliograph, which up to the present time has only given us pictures 4 inches in diameter, has been altered, as was suggested two years ago by the Solar Physics Committee, so as to take pictures of 8 inches. This necessitated a new micrometer which has already been constructed. Again, the photographs taken in India under the auspices of the Solar Physics Committee are now sent to Greenwich to be reduced with those of the previous series, and the result is a considerable increase in the number of days for which photographs are available. Thus in the year 1883 the 215 days of Greenwich are supplemented by 125 days of India, making a total of 340 out of 365 days. In 1882 we had Greenwich, 201, India 142, making up 343.

There is nothing new to remark with regard to magnetical work. We may state however that the magnetic elements for the past year were determined to be as follows:—

Approximate mean westerly declination	18° 25′.
Mean horizontal force .	3·926 (in English units). 1·810 (in metric units).
Mean dip	67° 31′ 10″ (by 9-inch needles). 67 31 36 (by 6-inch needles). 67 31 59 (by 3-inch needles).

The doings of the Deal time-ball and Westminster clock are thus referred to:—

"As regards the Deal time-ball, after various delays the arrangement, referred to in the last Report, for sending a current to Deal and receiving a return-signal through the chronopher of the Post Office telegraphs, was brought into operation on February 29, and has worked well since. The change has necessitated some slight alteration in our arrangements in order that we may be able to receive the Westminster signal through the same wire which is now used for the Deal current and its return signal. There have been 16 cases of failure in the dropping of the Deal time-ball owing to interruption of the telegraphic connections, 12 under the old system, and 4 since the new arrangement with the Post Office. On 19 days the current was weak and required the assistance of the attendant to release the trigger, and on 9 days the violence of the wind made it imprudent to raise the ball.

"The errors of the Westminster clock have been under 1s. on 53 per cent. of the days of observation, between 1s. and 2s. on 30 per cent., between 2s. and 3s. on 13 per cent., between 3s. and 4s. on 3 per cent., and between 4s. and 5s. on 1 per cent."

THE NORTH CAPE WHALE

THE North Cape or Biscay whale belongs to the group of true *Balænæ*, or smooth whales, *i.e.* those whales which have no fin on the back or furrows along the throat, as is the case with the so-called fin-whale group. It has most in common with the South Sea whale (*Balæna australis*). Its systematic name is *Balæna biscayensis* (Eschricht).

The habitat of the North Cape whale is limited to the north temperate zone of the Atlantic Ocean, whereas the Greenland whale is found most frequently in the closer vicinity of the Pole. Along the coasts of Europe the North Cape whale used to be found from the Mediterranean to the sea north of Norway, as far as the Beeren Island. Its true home, was, however, according to earlier writers who have dealt with the whale-fisheries in the preceding centuries, between Iceland and Norway, its original name—the North Cape whale—being derived from its frequent appearance around that promontory some centuries ago.

It visited the coasts of Central and South Europe regularly during the winter months, its favourite haunt appearing to be the Bay of Biscay. There it began to be pursued very early—perhaps as far back as the eleventh or twelfth century. In the fourteenth century the whale-fishery was an established industry here. It was also, according to the Icelandic Saga, "Kongespeilet," written in the twelfth century, already at that period largely caught by the Icelanders. It was called by the latter *slätbag* (smooth-back), and it was in all probability the catching of the North Cape whale of which the bard Othar of Haalogaland, *i.e.* Nordland in Norway, gave such an interesting account before King Alfred the Great of England. He stated that its haunts were then the shores of Northern Norway.

The principal expeditions for catching the whale were, however, despatched from the Bay of Biscay, but as it became more and more scarce in this part, it was followed as far as Iceland, where the Biscay fishermen found formidable rivals in the old Icelanders. It was these expeditions to Iceland which brought the Greenland whale under the notice of the southerners, and from the beginning of the seventeenth century the Greenland whale fishery around Spitzbergen became the leading industry.

In the middle of the seventeenth century the Americans began to catch whales. The Biscay whale was then very plentiful around the east coast of North America, and from the ports of "New England" numerous expeditions

for hunting this species were yearly despatched. The Americans called it "black whale," a denomination which, by the bye, also applies to other kinds.

Its range on the shores of America seems to have fallen a little south of that of Europe. It is in fact most probable that the whale visited the coast of Florida during the winter months, perhaps even more southern latitudes. Northwards it might be found as far as the sea is free from ice, but several circumstances seem to indicate that it preferred a temperate zone, and that its appearance on the shores of Greenland were merely migratory visits during the hot season. It may in fact be assumed that the North Cape whale made its regular migrations like the Greenland whale; in support of which I may point out that from the thirteenth to the fifteenth centuries the whale-hunting in the Bay of Biscay was carried on only during the winter months, and around America was limited to the season between November and April, at all events on the coast of New England.

What is known as to the principal haunts of this species of whale is alone based on the reports we possess of its hunting in the preceding centuries.

From the eighteenth century we hear no more about the catching of the North Cape whale in European waters, and in the beginning of the present century it also ceased to be hunted on the shores of America in consequence of its great scarcity.

It is therefore exceedingly interesting to find that the North Cape whale is again appearing on the east coast of America in such numbers that its catching is being resumed.

On the coasts of Europe the whale has only been discovered twice during this century, viz. in 1854, when a young one was caught at Pampeluna, the mother escaping; and in 1877, when the carcass of one—thirty-six feet in length—was cast ashore in the Bay of Toronto in Southern Italy. The skeleton of the former was brought to Copenhagen by the late Prof. Eschricht, where it now is.

The discovery which I made in 1882 on the shores of Finmarken of remains of this species of whale, hunted there by the Dutch in the sixteenth century, gave rise to further investigations as to the probable reappearance also in these parts of the North Cape whale, and from reports and circumstances brought to my knowledge, I feel convinced that considerable numbers of the North Cape whale again yearly appear on the coast of Northern Norway, where they were once so common. I must indeed regret that to ascertain with positive certainty whether this is a scientific fact is very difficult for a scientist whose stay in a certain part for scientific research is limited to a month or so. I hope, however, to obtain substantial proof of my belief at no very distant date.

For a figure of the North Cape whale I may refer the reader to that published in May 1883 in the *Bulletin* of the American Museum of Natural History, New York.

The University, Christiania G. A. GULDBERG

MEASURING EARTHQUAKES

I.—METHODS

IT is difficult to define the word earthquake in terms which will not cover cases to which the name is inappropriate. To say that an earthquake is a local disturbance of the earth's crust, propagated by the elasticity of the crust to neighbouring portions, is true, but the definition does not exclude, on the one hand, such tremors of the soil as are set up by the rumbling of a carriage, by the tread of a foot, or even by the chirp of a grasshopper, nor, on the other, those slow elastic yieldings which result from changes of atmospheric pressure, from the rise and fall of the tides, and perhaps from many other causes. One writer, in his definition of the word, limits the name earthquake to disturbances whose causes are unknown—a course open to the obvious objection that if the study of earthquakes ever advanced so far as to make the causes perfectly intelligible we should, by definition, be left with no earthquakes to study. It must be admitted, however, that in the present state of seismology this objection has no force, for in assigning an origin to any disturbance likely to be called an earthquake, we have, so far, been able to do little more than guess at possibilities. The more practicable task of determining what, at any one point within the disturbed area, the motions of the ground during an earthquake exactly are has lately received much attention, and in this department of seismology distinct progress has been made.

Apart from its scientific interest, this absolute measurement of earthquake motion is not without its practical use. Though the recent sharp earthquake in the Eastern Counties has reminded us that no part of the earth's surface can be pronounced free from liability to occasional shocks, these occur so rarely in this country that English builders are little likely to let the risk of an earthquake affect their practice. If Glasgow or Manchester had

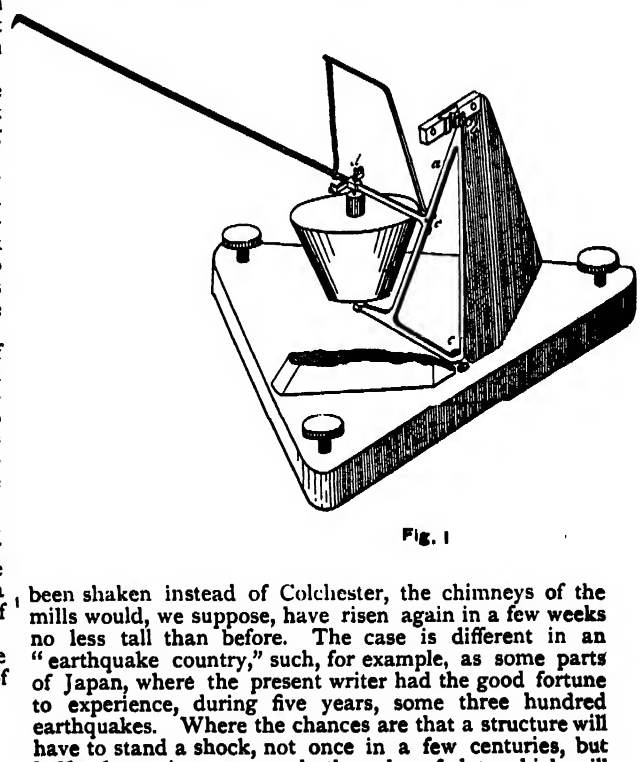

FIG. 1

been shaken instead of Colchester, the chimneys of the mills would, we suppose, have risen again in a few weeks no less tall than before. The case is different in an "earthquake country," such, for example, as some parts of Japan, where the present writer had the good fortune to experience, during five years, some three hundred earthquakes. Where the chances are that a structure will have to stand a shock, not once in a few centuries, but half-a-dozen times a month, the value of data which will enable an architect or engineer to calculate the frequency and amplitude of the vibrations, and the greatest probable rate of acceleration of the earth's surface, does not need to be pointed out.

To know how the earth's surface moves during the passage of a disturbance we must obtain, as a standard of reference, a "steady-point," or point which will remain (at least approximately) at rest. This is a matter of no small difficulty, for (as will be shown in a second paper) the motions during any single earthquake are not only very numerous but remarkably various in direction and extent. Most early seismometers were based on the idea that an earthquake consists mainly of a single great impulse, easily distinguishable from any minor vibrations which may precede or follow it. The writer's observa-

tions of Japanese earthquakes do not bear this out. They show, on the contrary, during the passage of almost every earthquake, scores of successive movements, of which no single one is very prominently greater than the rest. Moreover, the direction in which a particle vibrates is so far from constant that it is usually impossible to specify even roughly any particular direction as that of principal movement. For these reasons attempts are futile to obtain knowledge of earthquake motions from instruments intended to show only the greatest displacement or "the direction of the shock." The indications of such instruments are, in fact, unintelligible, and it is safe to say that no seismometer is of value which does not exhibit continuously the displacement of a point from its original position during the whole course of the disturbance. The value of the observation is enormously increased if, in addition to the amount and direction of the successive displacements being shown, these are recorded in their relation to the time. We can then, besides seeing the frequency of the vibrations, calculate the greatest velocity of the motion of the surface, and also its greatest rate of acceleration—an element of chief importance in determining an earthquake's capacity for mischief, since in a rigid and rigidly founded structure the shearing force through the base is equal to the product of the acceleration into the mass, and the moment tending to cause overthrow is that product into the height of the centre of gravity.[1]

the direction in which the piece is free to move, the support, which is rigid, moves with it, but the centre of percussion of the pivoted piece remains approximately at rest, and so affords a point of reference with respect to which the earth's movements may be recorded. If we could get rid of friction, and if it were practicable to have the equilibrium of the pivoted piece absolutely neutral, the centre of percussion would remain (for small motions) rigorously at rest even during a prolonged disturbance. But there must be some friction at the axis of support and also at the tracer which records the relative position of a point moving with the earth and the steady-point of the seismograph. And the pivoted mass must have some small stability, to prevent a tendency to creep away from its normal position during a long continued shaking, or in consequence of changes of the vertical. If, however, the mass be so nearly astatic that its free period of oscillation is much longer than the longest period of the earthquake waves, and if great care be taken to avoid friction, the centre of percussion behaves almost exactly as a true steady-point with respect to all the most important motions of even a very insignificant earthquake. The effective inertia of the system may be further increased by pivoting a second mass on an axis passing through the centre of percussion of the first piece and parallel to the axis of support. An instrument designed on these lines in which the pivoted pieces in neutral equilibrium were

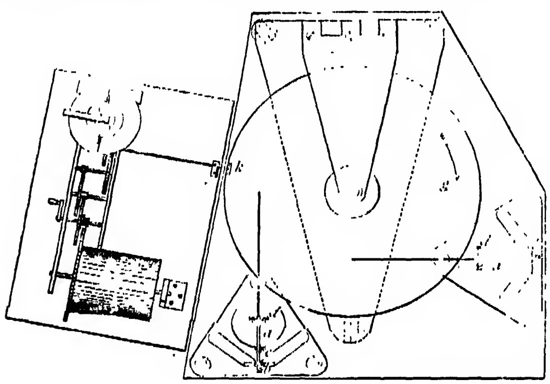

Fig. 2

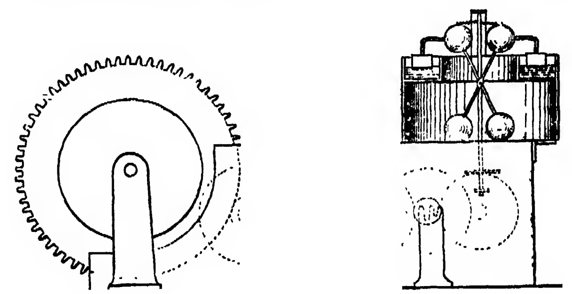

Fig. 3

Seismographs used during the last three or four years by the writer and others in Japan give a record of the earth's motion during disturbance by dividing that into three components, along the vertical and two horizontal lines. In the writer's apparatus these three are independently recorded on a revolving sheet of smoked glass, which is either maintained in uniform rotation, ready for an earthquake to begin at any moment, or is started into rotation (by help of an electro-magnetic arrangement) by the earliest tremors of the earthquake itself. The relative position of the marks on the glass serves to connect the three components with each other, and a knowledge of its speed of rotation connects them with the time. It is sufficient that the "steady-point" for each of the three components should be steady with respect to motion in one direction only. It may move with the earth in either or both of the other two directions, and in fact it is generally most convenient to provide three distinct steady-points, each with no more than one degree of freedom.

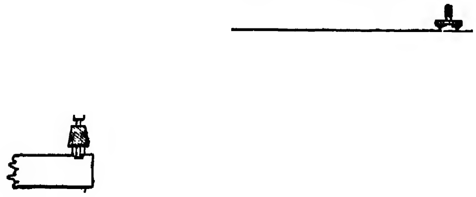
In that case each steady-point is obtained by pivoting a piece about an axis fixed to the earth, and in nearly neutral equilibrium with respect to displacements about the axis of support. When the earth's surface shakes in

[1] The case is different and much less simple where the structure is so flexible as to have a period of free vibration comparable with the periods of the earthquake vibrations.

two light frames supported as horizontal pendulums at right angles to each other, and with a massive bob pivoted at the centre of percussion of each, gave (in 1880) the earliest complete records of the horizontal movement of the ground during an earthquake. A description of it has been given in the *Proceedings of the Royal Society*, No. 210.

Figs. 1 and 2 show this seismograph, improved in many of its details. The form shown is one which has done excellent service in a seismological observatory which the writer was enabled to establish in the University of Tokio, through the interest of the Japanese directors. A similar instrument has also been supplied to the Government of Manila. Fig. 1 shows one of the two horizontal pendulums with a portion of one of its upright supports removed. The axis of support (which slopes very slightly forward to give a small degree of stability) is formed by two steel points, *b* and *c*, working in an agate V-groove and a conical hole. The frame of the pendulum is a light steel triangle, *a*, the effective inertia being given almost wholly by a second mass pivoted at *d* on a vertical axis which passes through the centre of percussion of the frame. The tracer, which serves to magnify as well as to record the motion, is a straw, tipped with steel, and attached to the pendulum by a horizontal joint at *d*, which allows it to accommodate itself to any inequalities in the height of the glass plate on which its distant end rests. A portion of its weight is borne by a spring, adjustable by a

clamp at e, by which the pressure of the tracer on the glass plate may be reduced to an amount just sufficient to scratch off a thin coating of lamp-black with which the glass is covered. In Fig. 2 the two pendulums are seen in plan, with their tracing pointers touching the glass plate g at different distances from its centre. The plate and pendulums are mounted on a single base, which is very rigidly secured to the top of a broad post, stuck firmly in the earth and projecting only a few inches above the surface. Continuous rotation is communicated to the plate by a friction-roller, k, held in a slot guide and connected by a universal joint to one of the arbors of a clock, which is wound up once a day. Government by an escapement being out of the question, the clock is controlled by a fluid-friction governor connected to the wheel train, also by friction gear, as shown in Fig. 3. The balls are four in number to prevent disturbance of them by an



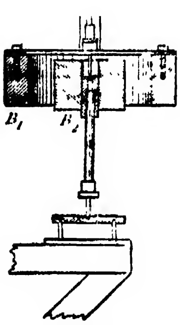


Fig. 4

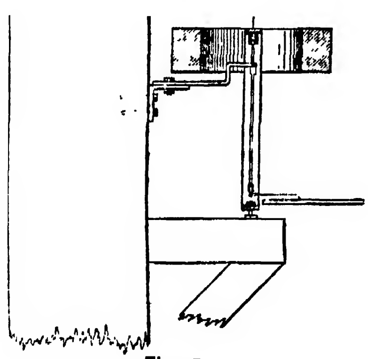

Fig. 5

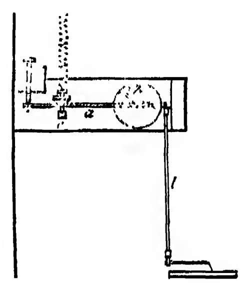

Fig. 6

earthquake. The vanes dip into oil, and are drawn back by two springs which tie them to the spindle.

When the earth shakes, the axis, d, of each bob remains sensibly at rest as regards components of motion perpendicular to the corresponding pendulum, and the tracing point is therefore displaced over the glass plate, in the direction of the plate's radius, through a distance which in this case is four times the motion of the earth. So long as no earthquake occurs each pointer traces over and over again a single circle on the plate. The circle frequently tends to widen inconveniently, especially if the pendulum is very nearly astatic. This is in part at least due to such changes of the vertical as have been observed by d'Abbadie, Plantamour, G. H. Darwin, and others. The plate consequently requires frequent attention, and where that cannot be given, an electric starting arrangement is to be preferred. When an earthquake has occurred, the plate is removed, varnished, and photographed by using it as a "negative."

The bob of each pendulum may of course be rigidly attached to instead of pivoted on the pendulum frame. In that case the centre of percussion of the frame and bob together (which will then be a little farther from the support than the centre of the bob) will be the steady-point. The writer, however, prefers the arrangement described above, which gives great compactness and a maximum of effective inertia, and which has the advantage of making the position of the steady-point at once determinate.

It would take too much space to describe or even to enumerate the many other devices which have been suggested to secure a steady-point by various methods of astatic support,[1] leaving one, or in some cases two, degrees of freedom to move horizontally. The horizontal pendulum has been modified by substituting a flexible wire and spring for its rigid pivots, thereby avoiding all but molecular friction at the axis of support. Spheres and cylinders, free to roll on plane or curved surfaces with or without a slab above them, have been tried, but their friction is excessive. The approximate straight-line motions of Watt and of Tchebicheff have been pressed into the service as means of suspending a mass with freedom to move in a horizontal path. The common or vertical pendulum, an old favourite with seismologists, has suffered many transformations in the effort to reduce its stability, which is preposterously great unless we make the pendulum very long. A 20-foot pendulum consisting of a cast-iron ring weighing half a hundredweight, hung

[1] See papers by Gray, Milne, the writer, and others in the *Transactions of the Seismological Society of Japan*, vols. i. to vi.; or a memoir on "Earthquake Measurement," published a year ago by the University of Tokio.

by three wires from a rigid tower, has done good work in the writer's observatory, but such an instrument has obvious drawbacks. Fig. 4 shows an arrangement, also used by the writer, and called a "duplex pendulum." A common pendulum with a ring bob, B_1, is connected to an inverted pendulum, B_2, by a ball-and-tube joint, which compels the bobs to move horizontally together. The combination can be made as nearly astatic as may be desired by proportioning the masses of the bobs to the lengths of the suspension-rods. The inverted pendulum stands on a joint which gives two freedoms to rotate but prevents twisting about a vertical axis; an extension of its rod upwards forms the multiplying arm, and carries a tracing pointer.

Another plan is shown in Fig. 5, which may be described as a duplex pendulum with a single bob, whose weight is borne partly by a socket below and partly by a spring from a support above. Any one of these instruments affords a single steady-point with respect to all motions in azimuth. Their principal use is to give "static" records of the horizontal motion, that is, records traced on *fixed* plates, which show at a glance the changes in direction of displacement during the occurrence of an earthquake.

In attempting to register the vertical component of earthquake motions, we meet with the difficulty that the weight of the mass whose inertia is to furnish a steady-point acts in the direction in which freedom of motion is to be retained. A weight hung by a spiral spring from a support above it is too stable to act as a seismometer, unless the spring be impracticably long. A horizontal bar fixed to a wall by a flexible joint and loaded at its end—an old device used by the British Association Committee at Comrie in 1842—is open to the same objection. If the loaded bar is rigid, but pivoted about a fixed horizontal axis, and held up by a spiral spring near the axis of support, we obtain a much slower period of free oscillation than if the spring were directly loaded with a weight which would stretch it to the same extent. Mr. Gray has rendered this device as nearly astatic as may be desired by adding a small tube containing mercury, whose effect is to increase the load when the bar goes down and to decrease it when the bar goes up. Another and simpler way of attaining the same result is shown in Fig. 6, which represents the vertical seismograph used in Japan by the present writer. There *a* is a horizontal bar pivoted about a horizontal axis on two points at *c*, with a heavy bob, *b*, whose weight is borne by a pair of springs, *d*. But the upward pull of the springs, instead of being applied to the bar in the line joining the axis *c* with the centre of gravity, is applied *below* that line by means of the stirrup *e*. Consequently, if the bar goes down, the pull of the springs, although increased above its normal value, is applied nearer to the axis, and (by properly adjusting the depth of *e* below the bar) the moment of the pull of the springs may thus be kept as nearly equal to the moment of the weight as may be desired—a condition which of course secures astaticism. The centre of percussion of the loaded bar is the steady-point, with respect to which the vertical motions of the ground are recorded by the multiplying lever *l* on the rim of a revolving glass plate, *o*, which may be the same plate as that which receives the record of the two horizontal components.

The instruments which have been briefly described succeed in registering very completely all the movements of the ground at an observing station during the occurrence of an ordinary earthquake, and some of them could be adapted with little difficulty to the registration of violent convulsions. It would be outside the scope of this paper to deal with the appliances by which Rossi and others have investigated those minute and almost incessant tremors of the soil whose very existence no observations less fine and careful would serve to detect.

J. A. EWING

NOTES

THE meeting for organisation of the American Association for the Advancement of Science will be held on Thursday morning, September 4; and on Friday evening, September 5, after the address of the retiring President (Prof. Charles A. Young, of the College of New Jersey), a general reception will be tendered by the citizens and ladies of Philadelphia to the members of the British and American Associations, and the ladies accompanying them. The British Association has been cordially invited, both by the American Association, to take part in their proceedings, and by the Local Committee representing citizens of Philadelphia, to accept the warm welcome which will be tendered them during the joint session. The Local Committee for the Philadelphia meeting is divided into a number of sub-committees, which have been specially created to render the stay of their visitors agreeable. It is earnestly requested that every one who intends to participate in this meeting will send his name, together with the number of ladies and gentlemen in his party, at as early a date as possible, to Dr. Persifor Frazer, Secretary of the Committee on Invitations and Receptions, 201, South Fifth Street, Philadelphia. During the week occupied by the session a number of receptions, entertainments, and excursions will be given, and a day will be set apart for the examination of the International Electrical Exhibition, to be held at Philadelphia, under the auspices of the Franklin Institute, and commencing September 2. By an arrangement between the Canadian and United States trunk lines, the members of the British Association will be furnished with first-class passage from Montreal to Philadelphia and return for 15 dollars (3*l.* 1*s.* 8*d.*), or for the single trip from Montreal to Philadelphia for 9 dollars (1*l.* 17*s.*). It is to be hoped that these rates will be further reduced before the members of the British Association will be ready to take advantage of them.

THE Executive Council of the International Health Exhibition have determined to hold an International Conference on Education in connection with the Education Division of the Exhibition: they have appointed a Committee of Management, who have drawn up a programme. For convenience of discussion all papers to be read will be printed beforehand, and they will subsequently be published by the Executive Council. Persons desirous of attending the Conference are invited to send in their names to Mr. R. Cowper, Secretary to the Committee of Management, International Health Exhibition, South Kensington, to whom any inquiries can be addressed. The following are the subjects for discussion:—1. Conditions of Healthy Education. 2. Infant Training and Teaching: (*a*) Kindergarten; (*b*) Instruction generally. 3. Technical Teaching: (*a*) Science; (*b*) Art; (*c*) Handicrafts; (*d*) Agriculture; (*e*) Domestic Economy. 4. Teaching of Music in Schools. 5. Museums, Libraries, and other Subsidiary Aids to Instruction in Connection with Schools. 6. Training of Teachers. Under this head will be considered the right professional preparation for teachers in (*a*) elementary, (*b*) intermediate and higher, (*c*) special and technical schools. 7. Inspection and Examination of Schools: (*a*) by the State; (*b*) by the Universities; (*c*) by other public bodies. 8. Organisation of Elementary Education. 9. Organisation of Intermediate and Higher Education. 10. Organisation of University Education. 11. Systems of Public Instruction in various Countries.

THE Albert Medal of the Society of Arts has been awarded by the Council of the Society, with the approval of the Prince of Wales (the President), to Capt. James Buchanan Eads, "the American engineer, whose works have been of great service in improving the water communications of North America, and have thereby rendered valuable aid to the commerce of the world."

THE death is announced of the celebrated Danish entomologist, Prof. J. C. Schiödte, at the age of sixty-nine.

THE St. Petersburg Academy of Sciences intends to publish the valuable documents which came into its possession from the great expeditions of the last century, of Krasheninnikoff, Müller, Pallas, and Messerschmidt; they are still unknown, as also the correspondence of the great explorers of Russia and Siberia.

A NEW scheme of a Polar expedition has been recently submitted by several officers of the Russian Navy to the Minister, Admiral Shestakoff. Starting from the idea that it is impossible to reach the North Pole by sea on account of the archipelagos that cover the circumpolar region, the Russian officers propose to start an expedition on sledges from the New Siberia Islands, which are 900 nautical miles distant from the Pole. This space is to be covered by sledge parties, who would make depots of provisions on the newly-discovered islands, and thus slowly but surely advance towards the north, securing at the same time the return journey of the expedition. When elaborated, the scheme will be submitted to the learned Societies, and the necessary money raised by subscriptions.

WE understand that the Commissioners under the new Universities (Scotland) Bill, if passed as it stands at present, will have power to establish, if they find it expedient, a Science Faculty in the Universities or in some of them, and to make provision for a curriculum or course of study in such Faculty which shall be coordinate with the curriculum or course of study in the Faculty of Arts. The Bill has the approval of the Senatus Academicus University of Edinburgh.

MR. JAMES JACKSON, the librarian of the Paris Geographical Society, has drawn up a useful table showing the extent to which the metrical system is used. In the following countries the system is legally obligatory:—

	Population		Population
Argentine Republic	2,830,000	Italy	28,459,451
Austria-Hungary...	37,786,346	Mexico	10,046,872
Belgium	5,520,009	Netherlands	4,172,971
Bolivia	1,957,352	Norway	1,806,900
Brazil	9,883,622	Paraguay	346,048
Chili	2,199,180	Peru ...	2,699,945
Colombia	4,000,000	Portugal	4,160,315
Denmark	1,969,039	Roumania	5,073,000
Equador	946,033	Spain ...	16,634,345
France & Colonies	46,843,000	Sweden	4,579,115
Germany	45,234,061	Switzerland	2,846,102
Greece...	1,979,305		
			241,973,011

In the following countries the metrical system is optional:—Canada, 4,324,810; United States, 50,419,933; Great Britain and Ireland, 35,241,482; Persia, 7,653,600; total, 97,639,825. In the following countries the system is often used without its having legal value:—

	Population		Population
	6,820,000	Uruguay...	438,245
India...	198,755,993	Venezuela	2,075,245
Russia	100,372,553		
Turkey	24,804,350		333,266,386

THE Duke of Norfolk has indicated his intention of contributing 3000*l.* towards the technical department of the Firth College, Sheffield.

THE East of Scotland Naturalists' Union held a very successful meeting in Dundee on Friday and Saturday last. Dr. Buchanan White gave an instructive and interesting address; various reports were given in, papers read, and a largely-attended *conversazione* held in the evening. On the Saturday a dredging excursion was made to the Bell Rock.

THE Manchester Field Naturalists have been spending the Whitsuntide holiday in Sherwood Forest. On the way to Mansfield, which was chosen as the head-quarters of the party, a short stay was made in the mountain limestone region of Derbyshire, to examine the geology of Brick Cliff. An interesting feature of the programme was the visit made to the Creswell Caves (in a pretty ravine of the magnesian limestone) under the guidance of the Rev. J. Magens Mello, one of the principal explorers of the caves, from which, it will be remembered, important remains of the post-Pleiocene Mammalia and Neolithic instruments have been obtained. The weather was very propitious, and the visit very enjoyable.

THE seventh annual meeting and *conversazione* of the Midland Union of Natural History Societies will be held at Peterborough on Wednesday, June 25. Excursions will be made to Stibbington Hall, Bedford Purlieus, and the Decoy in Borough Fen and Croyland on Thursday, June 26. The annual meeting will be held in the Fitzwilliam Hall, Peterborough, on Wednesday, June 25, at three o'clock, the President of the Union (the Very Rev. the Dean of Peterborough) in the chair. The business of the meeting will be to receive the Report of the Council and the Treasurer's accounts; to fix the place of the next annual meeting in 1885; to award the Darwin Medal for the year 1884; to consider any suggestions that members may offer; to discuss the work of the Union during the coming year; and to transact all necessary business. The President will open the meeting with an address.

MR. F. W. EASTLAKE of Tokio informs us that the well-known Devonian Brachiopod, *Spirifer disjunctus*, in common with several other Devonian genera such as *Rhynconella*, *Cornulites*, *Spirorbis*, and the like, is called by the Chinese *shi-yên* or "Stone Swallow," and that the powdered shell is largely sold by the native druggists as a specific in urinary and renal disorders. He has obtained a specimen of the shell from South Formosa, which he regards as indicating a prolongation of that Devonian formation which, commencing with Hainan and Southern China, is traceable throughout the Loochoos and the southern provinces of Japan. *Spirifer disjunctus* is not uncommon in the Mikado's Empire, but as it is highly prized on account of its supposititious medicinal virtues, it is possible, if not probable, that the fine specimens obtained from the Japanese were originally brought from China. The very fact that *Spirifer disjunctus* is one of the ornaments of the Eastern Asiatic pharmacopœia renders it unusually difficult to trace the locality whence the Brachiopod may have been brought.

THE new Scandinavian mathematical journal, *Acta Mathematica*, has already gained such a reputation that the French Government has decided to subscribe for fifteen copies for the Facultés des Sciences. In his note to the Swedish Ambassador in Paris on this subject M. Jules Ferry points out that it is the first time his Government has supported a foreign publication, which he trusts will be an acknowledgment of the high international position the *Acta Mathematica* has gained and of the value it has become to French science. This journal is also supported by the three Scandinavian Governments.

WITH the brig *Lucinde*, which has just left Copenhagen, Lieut. Jensen of the Danish Navy, Dr. Lorentzen, and the painter Ris-Carstensen, left for Greenland for the purpose of measuring, and exploring geologically and geographically, the country between Holstensborg and Sukkertoppen, the shore of which is very broad—it is estimated about sixty miles. As this part of Greenland has never been visited by Europeans, our knowledge of its natural condition is limited. The natives state that there are deep fjords here, and great high plateaux partly covered with glaciers.

ON May 14, at 12.30 a.m., a remarkable phenomenon was observed at Nyköping in Sweden. The weather was dull and

rainy, when suddenly streamers of light were seen in the northern sky running from west to east. They were seen twice, the first time lasting about a minute, but the second very short. The light was so intense that the streets became quite light.

THE Museum of the Kendal Literary and Scientific Institution possesses a valuable series of Carboniferous fossils. Most of the zoological groups are well represented, especially in relation to Brachiopoda and Gasteropoda, the former containing large examples of *Productus giganteus*, Martin, and the latter important specimens of *Euomphalus crotolostomus*, M'Coy, and *Phanerotinus cristatus*, Sowerby. The fossils are chiefly local, many of them having been collected by the once well-known geologist of Kendal, John Ruthven, who prepared the geological map for Miss Martineau's "English Lakes." This collection has recently been named, classified, and catalogued by Mr. R. Bullen Newton, F.G.S.

IN the letter by M. Antoine d'Abbadie in NATURE for May 29 (p. 101), the passage, "it was then 24m. 8s. past midnight," should be omitted.

THE additions to the Zoological Society's Gardens during the past week include two Squirrel Monkeys (*Chrysothrix sciurea* ♂ ♀) from Brazil, presented by Mr. Robert Thom; two Black-eared Marmosets (*Hapale penicillata* ♂ ♂) from South-East Brazil, presented by Mr. C. D. Middleton; a Common Squirrel (*Sciurus vulgaris*), British, presented by Mrs. Grover; a Marsh Ichneumon (*Herpestes galera*), a Dusky Ichneumon (*Herpestes pulverulentus*) from South Africa, presented by Dr. Holub, C.M.Z.S.; two Sociable Vultures (*Vultur auricularis*) from Africa, an Angolan Vulture (*Gypohierax angolensis*) from West Africa, presented by Sir Donald Currie; a Gray Amphisbæna (*Blanus cinereus*) from Spain, presented by Mr. W. C. Tait, C.M.Z.S.; a Burchell's Zebra (*Equus burchelii* ♀) from South Africa, two Common Camels (*Camelus dromedarius*) from Egypt, five Horned Lizards (*Phrynosoma cornutum*) from North America, deposited; five Goldeneyes (*Clangula glaucion*), five Common Snakes (*Tropidonotus natrix*), twenty-four Green Lizards (*Lacerta viridis*), European, purchased; a Japanese Deer (*Cervus sika* ♀), a Mexican Deer (*Cervus mexicanus* ♀), a Long-fronted Gerbille (*Gerbillus longifrons*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE OBSERVATORY OF PARIS.—Admiral Mouchez's report on the state of this establishment and the work accomplished therein during the past year commences with some details of his scheme for erecting a succursal observatory at a distance from Paris, where the disadvantages of location in the midst of a great city would be avoided. His proposal was to dispose of a part of the actual grounds of the Observatory, a step which would be likely to realise a sum adequate to the erection of the new building, at the same time retaining the present one to form the head-quarters of the Bureau des Calculs, the Archives, and the Museum, the two establishments to remain under the same direction and to constitute together the Observatory of Paris. This scheme, it is known, has not met with general acceptance at the hands of the scientific authorities.

M. Lœwy, in charge of the Meridian Service, has been occupied with the reobservation of stars in the Catalogue of Lalande, while a large number of observations of the sun, moon, and planets has also been made, eighteen observers taking part in this work in the course of the year. The equatorials of 12 and 14 inches aperture and the equatorial *coudé* were employed on observations of comets and small planets. The Ecliptical Charts Nos. 12, 19, 48, and 67 have progressed, and attention has been paid to double-star measures. M. Mouchez reports that the construction and installation of the great telescope (0·74 m.) has been retarded by the difficulty of establishing it in the grounds of the Observatory at Paris. In the Department of Astronomical Physics MM. Thollon and Trépied had been occupied for six weeks on the Pic du Midi, where, with M. Naussinat, in present charge of the Observatory, they studied the advantages of the station, more especially for solar observations, concluding that great scientific interest would attach to work that might be accomplished during the four or five weeks of the fine season in a small observatory at that point. Funds for the purpose are not yet available.

M. Mouchez further reports upon the distribution of time in Paris, the additions to the Museum during the year, which consist of instruments of the last century found in the Observatory of Toulouse, a portrait of Copernicus, &c.; the work of the Bureau des Calculs, which remains in charge of M. Gaillot; the publications of the Observatory during the year, including vol. xvii. of the *Annales*, in which are some important memoirs theoretical and practical; and the personal work of the staff.

A plan of the grounds of the Institution is appended, on which are distinguished those portions which M. Mouchez had proposed to alienate with the view to providing means for the erection of an observatory at a distance from Paris.

THE GREAT COMET OF 1882.—In an appendix to the Washington Observations, 1880, is an account prepared by Mr. W. C. Winlock, at the desire of the Superintendent of the Naval Observatory, Admiral Shufeldt, on the great comet of 1882 as observed at Washington, first with the 9·6 inch and subsequently with the 26-inch refractor. The latest date on which the comet's position was determined is April 4, 1883. Micrometrical measures of the nucleus were made on a number of evenings, and from a plate showing its aspect and formation between February 1 and March 3 the difficulty of deciding upon the proper point for observations of position, owing to the existence of several almost equally luminous condensations in the head of the comet, is very apparent. For a similar reason, in another plate the points observed with the transit-circle from September 19 to March 3 are shown. There has rarely, if ever, existed a greater need for precautions of this nature, to assist in the combination of the places obtained at various observatories, for the accurate determination of the orbit. The comet was first seen at Washington shortly after noon on September 19, and was visible for several hours to the naked eye about twenty-eight minutes preceding the sun and 1°·2 further south. In the 9·6-inch equatorial "it presented the appearance of a bird with wings extended," a description that applies to other comets that have been seen in daylight or in a very strongly illuminated sky, as for instance the first comet of 1847, figured in Johnston's "Atlas of Astronomy."

GEOLOGICAL NOTES

CANADIAN COALS AND LIGNITES.—Dr. G. M. Dawson collects and publishes, chiefly from the Reports of the Geological Survey of Canada, some useful Notes on the Coals and Lignites of the Canadian North-West. These mineral fuels are all of Cretaceous and Tertiary age. They are extensively developed near the Bow and Belly Rivers and their tributaries, extending eastward from the base of the mountains to about the 111th meridian; but as this is the only region yet examined in detail by the Survey, there may yet prove to be other districts of equal value. Where the Cretaceous rocks have been much disturbed and folded, the coal passes into the condition of anthracite, of which a seam occurs on the Cascade River near its confluence with the Bow River and close to the line of the Canadian Pacific Railway. Out on the plains, however, the strata are nearly flat, and as they recede from the mountains the coals show a larger percentage of water, and assume more or less completely the character of lignites.

BELGIAN ERRATICS.—To the already cited examples of fragments of Scandinavian rocks in the post-Tertiary deposits of Belgium Mr. E. van den Broeck has recently added the discovery of a piece of granite (measuring 0·8 × 0·5 × 0·6 metre) in the most northern part of the kingdom, embedded in the fine Campinian sands of Wortel—apparently the first Belgian example of any fragment large enough to claim perhaps the name of an erratic block (*Ann. Soc. Géol. du Nord*, xi. p. 2).

POSITION OF THE CALLOVIAN ROCKS.—M. Paul Choffat protests against the inclusion of the Callovian among the Upper Jurassic formations, as was decided at the last Conference of the International Commission on Geological Nomenclature. This decision, based on the palæontological affinity of the Callovian and Oxfordian stages he believes to be theoretically false and to be practically impossible of application in any general map of the whole of Europe. He gives a *résumé* of obser-

vations which in his opinion demonstrate that in the chain of the Jura, the east of the Paris basin, and in Portugal the lower part and even the whole of the Callovian are locally replaced by an extension of the Bathonian deposits.—(*Jornal de Sciencias Mathematicas*, &c., Lisboa, No. xxxvii., 1884.)

THE GLACIAL BOUNDARY IN OHIO.—Prof. G. F. Wright has for ten years past been studying the glacial phenomena of the Eastern States of the Union. Beginning with the kames of the Merrimac Valley in Eastern Massachusetts, he has followed the last edge of the glacial trail from the Atlantic border across to the southern part of Illinois. How much further he may have to trace it westwards he is at a loss to know. Meanwhile he gives an interesting outline of his labours in a pamphlet just issued by the Western Reserve Historical Society of Cleveland, Ohio. The edge of the deposits left by the ice-sheet of the Glacial Period or "terminal moraine," as the American geologists call it, has been traced by him from the western part of Pennsylvania across the southern counties of Ohio and the northern margin of Kentucky to near the Miami and Ohio Rivers. It then enters Indiana and makes a great northward sweep as far as Martinsville, a little south of Indianapolis, whence it turns south-westwards and passes into Illinois a little above the confluence of the Wabash with the Ohio. The Report gives detailed maps of the "moraine" in its passage across Ohio, with descriptions of the nature and form of the drift ridges in the different counties and townships.

HYPERSTHENE-ANDESITE AND TRICLINIC PYROXENE IN AUGITIC ROCKS.—The United States Geological Survey has begun the issue of a *Bulletin* designed to appear from time to time in single parts, each containing a single paper complete in itself. These papers are to be such as relate to the general work of the Survey, but do not properly come within the scope of the Annual Reports or Monographs. The first number is devoted to the rocks of Buffalo Peaks, Colorado. A sketch of their geology by Mr. Emmons, the geologist in charge of the Rocky Mountain Division of the Survey, is followed by a detailed description of some volcanic masses by Mr. Whitman Cross, in which he continues his interesting researches on pyroxenic rocks. As fragments among the beds of tuff and likewise in place on the shoulder of the main Buffalo Peak, there occur certain augite-andesites the microscopic study of which reveals some important peculiarities. The pyroxenic constituent shows that a rhombic mineral, probably hypersthene, is largely predominant, while a great number, if not all, of the remaining crystals must be considered as triclinic. The occurrence of triclinic pyroxene had already been detected by the author among the crystalline schists of Brittany. He has been led to re-examine many pyroxenic rocks (diabase, melaphyre, basalt, &c.) from widely separated localities, with the result of finding, in some common rocks from well-known localities, that the augite, when placed between crossed Nicol prisms, is extinguished at a very decided angle from the diagonals of the prism. This abnormal action he thinks must show either that the mineral in question is triclinic or that there is an "optical anomaly." Following the example of Fouqué, who isolated and analysed the normal augite and unsuspected hypersthene of the Santorin andesite, Mr. Cross isolated the rhombic pyroxene of the rock of Buffalo Peaks, and proved its crystalline form by examining detached crystals under the microscope. He likewise submitted it to chemical determination, which proved it to be true hypersthene. These researches induced him to test the character of the pyroxenic constituent in other andesites from all parts of the world. He has found that a rhombic pyroxene is much more abundant in porphyritic crystals than augite. He suggests the need of a reclassification of andesite rocks, of which he thinks three main groups may be distinguished. At one extreme are the varieties with a trachytic character rich in felspar, often containing quartz or tridymite, and with a more crystalline ground-mass. At the other extreme are some basalt-like masses, but with little or no olivine. The normal "augite-andesites" form the intermediate group.

KRAKATOA AND THE SUN-GLOWS

IN the last issue of the *Bulletin of the St. Petersburg Academy of Sciences* (vol. xxix. No. 2), M. Rykatcheff publishes a very interesting paper on the atmospheric waves produced by the Krakatoa eruption. General Strachey and Mr. R. H. Scott (NATURE, vol. xxix. p. 181) have already shown how the eruption must have produced an atmospheric wave which has been noticed by the barometers at many meteorological observatories. The wave was propagated in concentric circles, increasing in diameter until it reached the great circle; then, it contracted until reaching a point on the antipode of Krakatoa, whence the wave returned in the same way to its point of origin; then, gradually diminishing in intensity, it made for a second and third time its way around the earth. M. Rykatcheff now publishes the curve of the barograph of Pavlovsk for August 27 to 30, where the influence of the atmospheric wave is pretty well seen; and he discusses the results obtained from observations at thirty-one different stations (Pavlovsk, St. Petersburg, Berlin, Leipzig, Magdeburg, Brussels, Paris (I. and II.), Toulouse, Greenwich, Kew, Aberdeen, Stonyhurst, Liverpool, Glasgow, Falmouth, Armagh, Valentia, Georgia Island, Coimbra, and Toronto). It appears from these observations, when calculated according to Gen. Strachey's method, that is, by taking the time between two successive passages of the wave at the same station, that, for European stations, on the average the wave took 36h. 38m. to make its way around the earth when it was going from east to west, and 35h. 54m. when going from west to east. The accordance of the figures for different observatories is striking (excepting Tolosa), the greatest deviation from the average being only + 33m. and − 38m. in the first case, + 27m. and − 39m. in the second. The average speed would thus be: for the first wave, 303·3 metres, and 316·1 metres for the second. The calculated time of the Krakatoa eruption would be between 9h. 6m. and 9h. 42m. Krakatoa mean time; or, on the average, 9h. 23m. When the calculations are made on M. Wolf's method (which admits the same speed in both directions), the average speed of the wave is 334·3 metres, and the time of the eruption would be 10h. 39m. Krakatoa mean time. Finally, M. Rykatcheff makes the calculations by deducing both speed and time of eruption from observations made at two stations next to Krakatoa (Pavlovsk and St. Petersburg), and then he calculates from equations made for all other stations the error of the two observations. He receives thus 321·4 metres for the speed of the wave, and 10h. 16m. for the time of the eruption at Krakatoa. These results are more in accordance, he says, with the result obtained by Herr Wolf's method, and, combining both, M. Rykatcheff takes as probable 327·9 metres for the speed, and 10h. 27m. for the time of the eruption. As to the amplitudes of the oscillations of the barometers at different stations, they vary from 0·9 to 1·7 mm. and reach 2·5 mm. at Georgia Island.

To the *Meteorologische Zeitschrift* for 1884 Dr. G. Hellmann contributes a learned paper on the recent glows. No theory is advanced as to their origin, and the interest of the paper is mainly historical. The oldest reference to similar phenomena the writer has been able to discover is that of the Flemish physician, H. Brucæus, who, in 1570, dedicated a "Tractatus de Crepusculis" to Tycho Brahe. In this work occurs the passage: "Cum autem diluculum initium sumat, ubi aër splendescere incipit, idque eveniat cum lumen solis ab aëre, ob vapores permixtos crassiores, versus horizontem reflectitur, patet non in eadem distantia solis ab horizonte crepuscula semper incidere, quod non una sit semper aëris densioris sive vaporum, a quibus fieri possit radiorum reflexio, altitudo."

In the *Annales de Chimie et de Physique*, sixth series, vol. i. 1884, MM. Perrotin and Thollon deal with the same subject from the physical standpoint. They give an able *résumé* of the various accounts that have appeared, especially in NATURE, and seem on the whole disposed to accept the theory of the volcanic origin of the after-glows.

A correspondent, F. A. R. R., sends us the following communication on the subject:—

The matter projected into the upper atmosphere appears to have passed round the globe westwards with great velocity, and to have diffused itself towards north and south much less rapidly. A stratum of fine dust thus formed itself at an elevation probably exceeding the altitude of the known upper currents. This stratum caused the sun to look green or blue on the Gold Coast, in the West Indies, at the Sandwich Islands, in India and the Indian Ocean, and last, as late as September 24, in the Soudan, nearly a month after the eruption of Krakatoa. The moon and stars were frequently greenish in Europe in December and January, up to four months and a half after the eruption, and the sun whiter than usual towards setting. The finely divided matter which thus deprived the sun and moon of

part of the rays which go to form the compound white, was plainly of a different grain from the small particles commonly present in the sky, for these arrest the blue rays and scatter them, allowing the rays towards the red end of the spectrum a freer passage, so as to impress the eye with the predominant red colour of luminous objects seen through a long stretch of atmosphere. Since the declining sun in India turned strongly green, the particles competent to arrest the red rays must have exceeded, in the path of the rays, the ordinary blue-arresting particles in quantity or power. But as the sun approached close to the horizon, the lower atmosphere, by cutting off the more refrangible rays, reduced the green, and sometimes caused the red to predominate in the setting sun. The particles of a common blue haze cause the sun to set deep red. The volcanic dust particles may have exceeded in magnitude the particles which cause haze, and possibly the stratum may have contained particles which might be visible under the microscope. That this dust stratum was still present in the higher atmosphere in January was indicated by the greenish tinge of moon and stars. It was largely composed of particles of sufficient magnitude to reflect white light, for a little before sunrise the sky seemed clouded over with something resembling white cirrus haze; but like a film of dust on a mirror, or the floating dust in a room, it was not visible except at certain angles. Condensed vapour, or ice particles in a very fine state of division, would account for the persistent halo or corona of varying radius, but so also would particles of transparent pumice. Assuming the red-arresting stratum to have remained during the autumn and winter months at altitudes from forty to twenty miles, descending say 1000 feet per day during 100 days, the effects observed after sunset and before sunrise were only what might be expected to follow by reflection from the minute surfaces. In the case of ordinary cirrus, the tints up to half an hour after sunset are as follows: white, pale yellow, yellow, orange, pink, red, deep red; or the red only may be visible if the texture be thin and the early twilight strong. With a continuous red-arresting stratum, however, we must consider what influence its horizontal breadth, through which the sun's rays must pass when near setting, would have upon the light reflected from the western sky. At a height of thirty miles the sun would be shining through a great length of the stratum, as viewed from the elevated point, when it had already set on the earth immediately below. At this point, thirty miles above the earth's surface, supposing that to be the height of the stratum, the vapour of the lower air would not yet be strongly exerting its influence in arresting the blue rays, but the sheet of dust would exert its maximum power of stopping the red rays, and the light which survived best, and which from the earth's surface we should see reflected soon after sunset from above the western horizon, would be green. The stratum being so composed as to be capable of reflecting all kinds of light, but by its own action through a great breadth filtering out some of the less refrangible rays, as it did more powerfully in India when less attenuated, the reflected light of the sun above the western horizon, and indeed towards north and south as well, could not fail to be affected with an excess of green. As the sun sank still lower, viewed from the height of thirty miles, it would begin to be largely robbed of the blue and green rays by the ordinary lower atmosphere, and the next colour in the western sky would consequently be yellow, which would equally be reflected by the matter composing the stratum. The yellow would be the result of a competition between the red-arresting upper dust and the blue-arresting lower air. As the sun descended still lower, the power of the ordinary vapour-charged strata would assert itself, and the yellow would pass to orange, pink, and crimson, just as the colour of the sun seen from any eminence commonly changes in setting. The upper haze would merely reflect these naturally changing colours, but the later tints would be more striking as darkness increased. All the changes observed in the first after-glow are thus fully accounted for by larger than ordinary sky particles arresting red waves and the general mass of the stratum reflecting all rays falling upon it. The secondary after-glow would show similar gradations if the first were strong enough to emit much light, but the red in it would be most conspicuous, for the action of the lower air in eliminating blue would be more powerful than the thin veil of dust in eliminating red. There was, however, a distinct greening of the eastern sky on several occasions, signifying the approach of the secondary after-glow. The increase of apparent brilliancy of both glows as they sank westwards would of course be due to perspective.

THE FIXED STARS[1]

II.

I HAVE said that the angle between the stars is measured in terms of the scale, but the scale-value, in seconds of arc, may change by the effects of temperature and from other causes.

Bessel, in his researches on the parallax of 61 Cygni, determined by independent means the effect of temperature on his scale-value, and applied corresponding corrections to his observations. But he also took the precaution to employ two stars of comparison situated at right angles to each other with respect to the principal star, so that the effect of parallax would be at a maximum for one comparison star at the season of the year when it was at zero for the other, and *vice versâ*.

But in the course of previous researches I found that there were sources of error other than mere change of the temperature of the air, viz. differences of temperature in different parts of the instrument, and changes in the normal focus of the observer's eye, which exercised a very sensible influence on the results. It was necessary to devise some method by which these should also be eliminated.

DIAGRAM II.—Showing comparison stars employed in determining the parallax of α Centauri.

There is a very simple means of doing this. Instead of taking two comparison stars at right angles, take two comparison stars situated nearly symmetrically on opposite sides of the star whose parallax is to be determined—such, for example, as the stars a and β in Diagram II. Now observe these distances in the order a, β, β, a, on each night of observation; so that on each night the observations of both distances are practically made at the same instant. Then, whatever causes have combined to create a systematic error in the measurement of one of these distances, precisely the same causes must create precisely similar systematic error in the measurement of the other distance. Thus if, by the regular or irregular effects of temperature or by changes in the normal condition of the observer's eye, we measure the distance a too great, so for the simultaneous observations of the distance β we shall from precisely the same causes measure that distance too great also.

But the *difference* of the distances will be entirely free from all errors of the kind; and, if the distances are not quite equal, it is very easy to apply a correction on the assumption that the sum of the distances is a constant.

In Diagram II. the circle represents a radius of 2° surrounding the star α Centauri. The distance of the component stars α_1 and α_2 Centauri in the diagram is enormously exaggerated for the sake of clearness. Guided by the principles just explained, search was made for comparison stars in pairs symmetrically situated with respect to α Centauri, and otherwise favourably situated for measurement of parallax.

You will remember that from the effects of parallax all stars appear to describe small ellipses about a mean position; stars near the pole of the ecliptic describing nearly circles, and those

[1] Lecture on Friday evening, May 23, at the Royal Institution, "On Recent Researches on the Distances of the Fixed Stars, and on some Future Problems in Sidereal Astronomy," by David Gill, LL.D., F.R.S., Her Majesty's Astronomer at the Cape of Good Hope. Continued from p. 137.

near the ecliptic very elongated ellipses. Obviously, then, those pairs of stars are most favourable—other conditions being equal—which lie near the major axis of the parallactic ellipse. The dotted ellipse in Diagram II. represents the form of the parallactic ellipse; that is to say, the form of the apparent path which α Centauri must describe if it is affected by parallax. Of course the size of the ellipse is exaggerated—in fact in the diagram nearly 5000 times—therefore remember that the diagram represents only that which we can compute before we have observed, viz. the *shape* of the ellipse, or the relations of the lengths of the two axes; the *absolute* size has to be determined from the observations.

The most favourable couple of comparison stars in our drawing is that marked α and β—they are nearest to the major axis of the parallactic ellipse, and they are very symmetrically situated with respect to α Centauri.

Now turn to Diagram III. Here is exhibited the results of my measures on a very large scale—in a manner similar to that in which the height of the barometer for different hours of the day, or the comparative price of wheat at different seasons of the year or in different years, is now exhibited in the daily papers. Imagine the star α about a mile immediately below any point of that curve, and the star β rather over three-quarters of a mile immediately above the same point, and you would then have a diagram to scale.[1] The middle horizontal line represents the mean difference of these two distances, and each dot or mark on Fig. 1 of the diagram represents the variation of that distance according to each successive observation. The different kinds of dot represent measures made at different hour angles, or when the relation of the direction of measurement to the line joining the observer's eye is different. These different kinds of personal errors were separately investigated, and they were then allowed for and the observations were corrected accordingly.

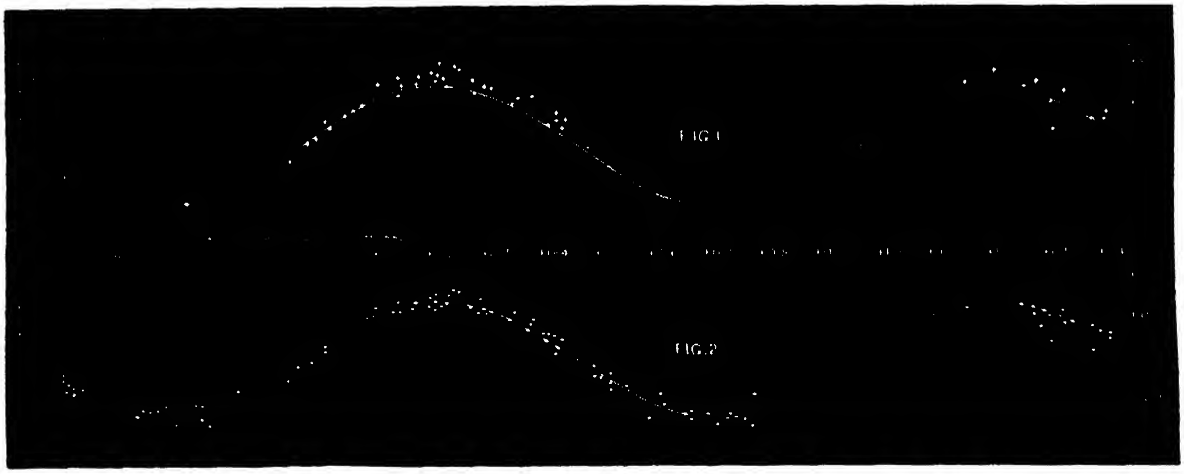

DIAGRAM III.—Curves showing the results of the observations of α Centauri relative to the comparison stars α and β.

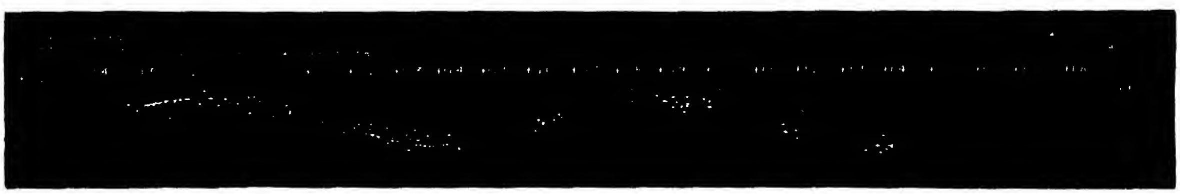

DIAGRAM IV.—Curve showing results of observations of Sirius for parallax.

DIAGRAM V.—Curve showing results of observations of ε Indi for parallax.

The observations so corrected are represented in Fig. 2, where each black dot expresses the result of the observations of a single night, and the curve is the computed curve resulting from a mathematical discussion of the observations.

You must be careful to understand that this is not simply the kind of curve which best represents the observations. The curve is limited by purely geometrical conditions to have its maximum on March 7 and its minimum on September 10, and to follow a precise form of curve according to a simple law. The observations only determine the range from maximum to minimum, and yet you see how perfectly the maximum of the observations agrees with the maximum of the curve, and the minimum of the observations with the minimum of the curve, and how closely the law is followed throughout.

The result was that from these observations the parallax of α Centauri was 0″·747, or practically three-quarters of a second of arc.

But I was not content with this result alone. I wished further confirmation, and selected another pair of stars, α′ and β′, shown in Diagram II.

[1] In the wall diagram one second of arc was represented by about 15 inches.

From similar observations with these comparison stars I obtained for the parallax of α Centauri $0''\cdot760$, a result which is identical with the last within the limits of the probable error of either.

My friend Dr. Elkin selected the stars $a\ b$ and $a'\ b'$ as his comparison stars, and in a precisely similar way he obtained as the mean of his results a parallax of $0''\cdot752$, a result identical with my own, so that we may conclude as one of the most certainly established facts of astronomy that the parallax of α Centauri relative to an average star of the seventh or eighth magnitude is three-quarters of a second of arc.

It is therefore beyond all doubt that Henderson's discovery was a real one. Herschel's verdict must therefore be confirmed, and the palm for first breaking down the barriers that separated us from any knowledge of the distances of the fixed stars be accorded to the memory of the Cape Astronomer Henderson.

So far as all existing researches go, α Centauri is the nearest of the fixed stars. Regarding the faint comparison stars as practically infinitely distant, let us try to realise how near or how far distant α Centauri really is.

There are, of course, an infinite number of illustrations which one might employ to convey some idea of such a distance. I shall content myself with one of them—something akin to which has already been used by Dr. Ball within these walls.

We are a commercial people, we like to make our estimates in pounds sterling. We shall suppose that some wealthy directors have failed in getting Parliamentary sanction to cut a sub-Atlantic tunnel to America, and so for want of some other outlet for their energy and capital they construct a railway to α Centauri. We shall neglect for the present the engineering difficulties—a mere detail—and suppose them overcome and the railway open for traffic.

We shall go further, and suppose that the directors have found the construction of such a railway to have been peculiarly easy, and that the proprietors of interstellar space had not been exorbitant in their terms for right of way. Therefore, with a view to encourage traffic, the directors had made the fares exceedingly moderate, viz. first class at one penny per 100 miles.

Desiring to take advantage of these facilities, an American gentleman, by way of providing himself with small change for the journey, buys up the National Debt of England and of a few other countries, and, presenting himself at the booking-office, demands a first-class single to α Centauri. For this he tenders in payment the scrip of the National Debt of England, which just covers the cost of his ticket; but I should explain that at this time the National Debt, from little wars coupled with some unremunerative Government investments in landed property, had run up the National Debt from 700 millions to 1100 millions sterling. Having taken his seat, it occurs to him to ask—

At what rate do you travel?

Sixty miles an hour, sir, including stoppages, is the answer.

Then when shall we reach α Centauri?

In forty-eight million six hundred and sixty-three thousand years, sir.

Humph, rather a long journey.

But enough of joking. If we wish to deal with distances so immense, we must adopt a more convenient unit of measure.

The most convenient unit for our purpose is the number of years that light would take to reach us. Light takes almost exactly 500 seconds of time to come from the sun; this is a figure easy to remember, and is probably exact to a single unit. The sun is ninety-three millions of miles distant, and this figure I believe to be exact within 200,000 miles.

Quite recently the accuracy of these figures has been confirmed in a very remarkable way by different kinds of investigations by different observers; otherwise I should not have quoted them with so much confidence.

The parallax of α Centauri is three-quarters of a second of arc; therefore its distance is 275,000 times the distance of the earth from the sun, and therefore light, which travels to the earth from the sun in 500 seconds (*i.e.* in $8\frac{1}{3}$ minutes) would take 4·36, or a little more than $4\frac{1}{3}$ years to come from α Centauri.

You will find in the accompanying table a specific account of the other results which were arrived at by Dr. Elkin and myself by precisely similar means, and you will find on the wall diagrams representing my own detailed observations in the case of Sirius and ϵ Indi.

TABLE II.—*Results of Recent Researches on the Parallax of Stars in the Southern Hemisphere*

Name of Star	Observer		Annual proper motion in arc	Parallax	Star's distance in light units, or number of years in which light from star would reach the earth	Velocity of star's motion in miles per second at right angles to line of sight
α Centauri ...	G. & E.		$3''\cdot67$	$0''\cdot75$	4·36	14·4
Sirius	G. & E.		1·24	0·38	8·6	9·6
Lacaille 9352	G.		6·95	0·28	11·6	73
ϵ Indi	. & E.	$5\frac{1}{4}$	4·68	0·22	15	63
o_2 Eridani ...	G.	$4\frac{1}{2}$	4·10	0·17	19	69
e Eridani ...	E.	$4\frac{1}{2}$	3·03	0·14	23	64
ζ Tucanæ ...	E.		2·05	0·06	54	101
Canopus ...	E.		0·00	Insensible		
β Centauri ..	G.		—	Insensible		

Time does not permit me to go into more detail as to each of these separate results, full of interest though they are, and each of them representing months of labour.

My object now is to generalise, to point out the conclusions that must be drawn from these two tables of parallax (Tables I. and II.), and to see what are the broad lessons that they teach us.

A glance is sufficient to show that neither apparent magnitude nor apparent proper motion can afford a definitive criterion of the distance of any fixed star—that different stars really differ greatly in absolute brightness and in absolute motion.

And now, what is the work before us in the future?

The great cosmical problem that we have to solve is not so much what is the parallax of this or that particular star, but we have to solve the much broader questions—

1. What are the average parallaxes of stars of the *first*, *second*, *third*, and *fourth* magnitudes, compared with those of fainter magnitude?

2. What connection does there subsist between the parallax of a star and the amount and direction of its proper motion, or can it be proved that there is no such relation or connection?

With any approximate answer to these questions we should probably be able to determine the law of absorption of starlight in space, and be provided with the data at present wanting for determining with more precision the constant of precession and the amount and direction of the solar motion in space. And who can predict what hitherto unknown cosmical laws might reveal themselves in the course of such an investigation?

It is important to consider whether such a scheme of research is one that can be realised in the immediate future, or one that can only be carried to completion by the accumulated labours of successive astronomers.

I have very carefully considered this question from a practical point of view, and I have prepared a scheme, founded on the results of my past experience. I have submitted that scheme for the opinion of the most competent judges, and in their opinion, as well as my own, the work can be done, with honest hard work for one hemisphere, within ten years. I have offered to do that work for the southern hemisphere with my own hands, and a proposal for the necessary instruments and appliances is now under the consideration of my Lords Commissioners of the Admiralty. I need hardly add that in this matter I look confidently for that complete consideration and that efficient support which I have never failed to receive at their hands since I have had the honour to serve them.

The like work will be undertaken for the northern hemisphere by my friend Dr. Elkin, who is now in charge of the heliometer at Yale College in America. It is at present the finest instrument of the kind in the world, and a photograph of it you have already seen upon the screen.

I most earnestly trust that we may be granted health and strength for this work, and that no unforeseen circumstances will prevent its complete accomplishment.

Before closing this lecture I wish briefly to allude to another engine of research in sidereal astronomy which quite recently

has received an enormous development, and whose application appears to offer a rich harvest of results. I refer to the application of photography to astronomical observation.

Your respected member, Mr. De la Rue, is the father of this method. Time does not permit me to dwell on his early endeavours and his successful results, but they are well known to you all. He opened up the field, and he cleared the way for his successors.

The recent strides in the chemistry of photography and the production of dry plates of extreme sensibility have permitted the application of the method to objects that formerly could not be photographed. Here, on the screen, are the spectra of stars photographed directly from the stars by Dr. Huggins, the lines which tell of the chemical constitution and temperature of the star's atmosphere being sharply defined.

Here are photographs of the great comet of 1882, which, with the cooperation of Mr. Allis of Mowbray, I obtained at the Cape, by attaching his ordinary camera to an equatorially mounted telescope, and with its aid following the comet exactly for more than two hours. Each one of the thousands of points of light that you see is the picture of a fixed star. The photograph suggests the desirability of producing star maps by direct photography from the sky.

Here on the screen is a photograph of the great nebula of Orion, or rather a series of photographs of it made by Mr. Common of Ealing. You will note the gradual development of detail by increase of exposure, and the wonderful amount of detail at last arrived at. Here are photographs from drawings of the same, and you will note the discrepancies between them. And here is a photograph of a star cluster also by Mr. Common.

No hand of man has tampered with these pictures. They have a value on this account which gives them a distinct and separate claim to confidence above any work in which the hand of fallible man has had a part.

The standpoint of science is so different from that of art. A picture which is a mere copy of nature, in which we do not recognise somewhat of the soul of the artist, is nothing in an artistic point of view; but in a scientific point of view the more absolutely that the individuality of the artist is suppressed, and the more absolutely a rigid representation of nature is obtained, the better.

Here is a volume compiled by one of the most energetic and able of American astronomers—Prof. Holden. It contains faithful reproductions of all the available drawings that have been made by astronomers of this wonderful nebula of Orion from the year 1656 to recent times.

If now we were to suppose one hundred years to elapse, and no further observation of the nebula of Orion to be made in the interval; if in some extraordinary way all previous observations were lost, but that astronomers were offered the choice of recovering this photograph of Mr. Common's, or of losing it and preserving all the previous observations of the nebula recorded in Prof. Holden's book—how would the choice lie? I venture to say that the decision would be—Give us Mr. Common's photograph.

Is it not therefore now our duty to commence a systematic photographic record of the present aspect of the heavens? Will not coming generations expect this of us? Does not photography offer the only means by which, so far as we know, man will be able to trace out and follow some of the more slowly developing phenomena of sidereal astronomy?

Huggins has shown how the stars may be made to trace in the significant cipher of their spectra the secrets of their constitution and the story of their history. Common has shown us how the nebulæ and clusters may be separately photographed, and it is not difficult to see how that process may be applied, not only to special objects, but piece by piece to the whole sky, till we possess a photographic library of each square half-degree of the heavens. But such a work can only be accomplished by consummate instruments, and with a persistent systematic continuity which the unaided amateur is unable to procure and to employ. It is a work that must be taken up and dealt with on a national scale, on lines which Huggins and Common have so well indicated, and which has already been put in a practical form by a proposal of Norman Lockyer's at a recent meeting of the Royal Astronomical Society.

I would that I had the power to urge with due force our duty as a nation in this matter, but my powers are inadequate to the task.

I employ rather the words of Sir John Herschel, because no words of mine can equal those of him who was the prose-poet of our science, whose glowing language was always as just as it was beautiful, and whose judgment in such matters has never been excelled. They were spoken in the early days of exact sidereal astronomy, when the strongholds of space were but beginning to yield the secret of their dimensions to the untiring labour and skill of Bessel, of Struve, and of Henderson. Think what they would have been *now* when they might have told how Huggins' spectroscope had determined the kinship of the stars with our sun, how it had so far solved the mysteries of the constitution of the nebulæ, and pointed out the means of determining the absolute velocity of the celestial motions in the line of sight. Think what Herschel would have said of those photographs by Common that we have seen to-night of that nebula that Herschel himself had so laboriously studied, and whose mysterious convolutions he had in vain endeavoured adequately to portray; and think of the lessons of opportunity and of duty that he would have drawn from such discoveries, as you listen to his words spoken forty-two years ago:—

"Such results are among the fairest flowers of civilisation. They justify the vast expenditure of time and talent which have led up to them; they justify the language which men of science hold, or ought to hold, when they appeal to the Governments of their respective countries for the liberal devotion of the national means in furtherance of the great objects they propose to accomplish. They enable them not only to hold out but to redeem their promises, when they profess themselves productive labourers in a higher and richer field than that of mere material and physical advantages.

"It is then, when they become (if I may venture on such a figure without irreverence) the messengers from heaven to earth of such stupendous announcements as must strike every one who hears them with almost awful admiration, that they may claim to be listened to when they repeat in every variety of urgent instance that these are not the last of such announcements which they shall have to communicate, that there are yet behind, to search out and to declare, not only secrets of nature which shall increase the wealth or power of man, but TRUTHS which shall ennoble the age and country in which they are divulged, and, by dilating the intellect, react on the moral character of mankind. Such truths are things quite as worthy of struggles and sacrifices as many of the objects for which nations contend, and exhaust their physical and moral energies and resources. They are gems of real and durable glory in the diadems of princes, and conquests which, while they leave no tears behind them, continue for ever unalienable."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The following are among the Readers and University Lecturers just now appointed:—Readers—Comparative Philology, Dr. Peill; Botany, Dr. Vines. University Lecturers—Comparative Philology, Mr. E. S. Roberts; Sanskrit, Mr. Neil; Mathematics, for Part 3 of the Tripos, Division A, Mr. Forsyth; Division B, Mr. Hobson; Division C, Mr. Glazebrook; Division D, Mr. J. J. Thomson; Applied Mechanics, Mr. Macaulay; Botany, Mr. F. Darwin; Animal Morphology, Mr. A. Sedgwick; Advanced Physiology, Dr. Gaskell and Mr. Lea; Histology, Mr. Langley; Geology, Mr. D. Roberts; Moral Science, Mr. Keynes.

Prof. Colvin has presented to the Fitzwilliam Museum between eight and nine hundred books on Classical Archæology, on behalf of certain members of the University, to be deposited in the library of the Museum of Classical Archæology.

A warm discussion arose on the 30th ult. in the Arts School, on the Report recommending the erection of new lecture-rooms and work-rooms for Biology and Physiology. Mr. Huddleston said the estimate of 3000*l.* a year ago had grown to 10,000*l.* now. He had hoped that finality was reached last year. Mr. Oscar Browning objected to the proposals that they were reckless and extravagant. Why not ventilate the present lecture-rooms, if they were so much used as was described? The proposal to buy 150 microscopes for 1000*l.* was one of the most ridiculous he ever heard of. Why should not each student bring his own? A science man's library was exceedingly small and inexpensive. Mr. Mayo thought sufficient accommodation might be provided by using the Museum of Zoology as a lecture-room for large classes. Mr. Sedgwick described the inconveniences felt in the late course of Elementary Biology, when 206 men had to pack

themselves where only 140 could properly sit. Many sat on the stairs, and in positions where they could not see the blackboard. Mr. Trotter urged that the medical students could not be expected to provide capital sums for buildings. The large class in Elementary Biology this year would want to attend Physiology next year. It was impossible that finality could be attained. Prof. Foster explained the serious inconveniences of requiring every student to bring his own microscope to these classes; they ought to belong to and remain in the laboratory. The difficulties that now arose had occurred because of past under-estimates. He had been laughed at a few years ago for suggesting that space for one hundred students of Physiology would be wanted soon. He had no lecture-room under his control, and no room in which he could give demonstrations to a large class, yet so important did he deem the practical work of the class in Elementary Biology that, if no new accommodation could be given to it, he should feel compelled to close the practical work of his own large class, and simply give lectures in Physiology, and give up his laboratory for the class in Elementary Biology.

SCIENTIFIC SERIALS

Journal of the Franklin Institute, No. 700, April.—Prof. Coleman Sellers, mechanics: introductory. Abstract report of a public lecture exposing various fallacies.—W. Dennis Marks, initial condensation of steam cylinders.—W. E. H. Jobbins, an investigation locating the strongest of the bronzes. The tests were made with Thurston's recording testing-machine, and gave for the two strongest bronzes the following:—Cu57, Zn42, Sn1, and Cu56, Zn42, Sn2.—J. C. Hoadley, a tilting water-meter.—S. Lloyd Wiegand, cast-iron in steam-boilers.—G. M. Bond, standards of length and their subdivision. W. Dennis Marks, economy of compound engines. Final agreement cannot be reached until "a more complete and rational set of experiments are made on the compound engine than now exist."—Dr. P. Frazer, reply to T. D. Rand's paper on the geology of Chester Valley, &c.

No. 701, May.—De Volson Wood, the most economical point of cut-off, a dialogue criticising Prof. Marks' paper.—J. P. Church, alleged remarkable error in the theory of the turbine water-wheel.—N. B. Clark, petroleum as a source of emergency power for war-ships. Proposes to employ furnaces into which petroleum is sprayed along with superheated steam and heated air.—S. L. Wiegand, cast-iron in steam-boilers.—R. Grimshaw, hanging the levers for indication.—R. Grimshaw, doctoring indicator cards.—Pliny Earle Chase, the sun-earth balance. This paper briefly expounds the author's views about harmonic relations in the solar system, and deduces values from them for the earth's mean radius of orbit, and for the weight of the sun.—G. M. Bond, standards of length and their subdivision.

Annalen der Physik und Chemie, Band xxi. No. 4, April, 1884.—G. Hansemann, on the diffusion of gases through a porous partition. The author concludes that Stefan's theory is not confirmed, but finds that the gaseous molecules within the pores offer a much greater mutual resistance than Stefan supposed.—G. Kirchhoff, on the theory of the diffusion of gases through a porous partition; a mathematical discussion of Stefan's theory.—Oskar Rother, on capillarity-measurements of salt solutions and their mixtures.—H. C. Vogel, remarks on Dr. O. Frölich's paper on the measurement of sun-temperature.—E. Warburg, on the electrolysis of solid glass. He concludes that in this obscure phenomenon the silica is not affected, and that the sodium only is moved electrically through the mass.—Emil Cohn, on the validity of Ohm's law for electrolytes.—A. Oberbeck, on electric oscillations: their magnetising action (part v.). The author concludes that undulatory currents exercise magnetising effects on iron and steel cores entirely as theory would indicate, provided account be taken of the internally induced currents.—L. Grunmach, absolute barometric measurements under a control of the vacuum by means of phenomena of electric illumination. The refusal of induction sparks to pass, or the phosphorescing of the glass surface, are chosen as indices of the exact state of the barometric vacuum.—W. Voigt, on the history of the Nobili-Guebhardt rings.

No. 5, May.—A. Winkelmann, on the diffusion of gases and vapours. This paper discusses the bearing of the formulæ of Meyer on certain changes in the coefficient of diffusion observed by Stefan's method.—L. Boltzmann, on a relation discovered by Bartoli between heat-radiation and the second law of thermodynamics.—L. Boltzmann, on the quantity of work which can be obtained in chemical combinations. An important discussion of formulæ, and bears on dissociation heat.—A. Overbeck, on electric oscillations, especially on their magnetising effect, and on the propagation of magnetic oscillations. Describes a method of experiment employing an electro-dynamometer, and concludes that the magnetic oscillations propagated along an iron rod decrease in amplitude at points successively distant from the origin of the oscillations, but that the magnitude of the decrement depends only on the quality of the iron, and is independent of its cross-section.—W. Hallwachs, on the electromotive force, the resistance, and the efficiency of secondary batteries. This paper, reprinted from the *Elektrotechnische Zeitschrift*, recounts researches by the author, and gives a summary of others by Tresca and Ayrton and Perry.—J. Stephan, on the calculation of induction-coefficients of wire coils. This paper re-discusses the formulæ used by Maxwell and by Lord Rayleigh for the cofficients of the coils used in the determination of the ohm.—J. Fröhlich, notice on the calculation of the potential of coils. This paper concludes with two convenient approximate formulæ for controlling more elaborate calculations.—S. Wleügel and S. Henrichsen, on the magnetism of organic bodies. Gives values for a number of alcohols.—J. Elster and H. Geitel, on the electricity of flame; a reply to J. Kollert.—H. Merczyng, on Fresnel's measurement of wave-length. The author contends that Fresnel never made his well-known determination with the well-known "Fresnel's mirrors," but by diffraction.—J. L. Andreæ, Boyle's law: a lecture-experiment. A thread of mercury is introduced into a long narrow vertical glass tube closed at the top, and hangs inclosing a certain volume of air permanently.—Carl Kirn, on a mercury interrupter with which the oxidation of the mercury is obviated. The contact is broken in a closed vacuous vessel.—G. Krebs, three ozone apparatus.—V. Pierre, apparatus for demonstration of the laws of elasticity of traction; apparatus for demonstration of the constitution of a longitudinal wave; galvanoscope for lecture-demonstration; apparatus for freezing water quickly under the air-pump. There is nothing very new in the first two of these. The galvanoscope is a simple modification of the vertical Bourbouze instrument. The air-pump apparatus is identical with forms often used in this country.

Bulletins de la Société d'Anthropologie de Paris, tome vi., série iii., 1883.—The conclusion of M. Ujfalvy's notes on the so-called Kaffir-Giapochs of Hindoo-Koosh, based on his own observations and those of Biddulph, Elphinstone, and other English authorities.—Communications from M. Ten Kate, on the results of his anthropometric observations of the Yaquis Indians of Sonora and Arizona; from M. Errington de la Croix, on the fish-eating modern cave-dwellers of the Island of Socotra; from M. Hamy, on the dental mutilations of the modern Huaxtecs; and from M. Manouvrier, on the force of the flexible muscles of the fingers in men and women, having reference to the weight of the brain at different anatomical and physiological periods.—On the Japanese races, by M. de Quatrefages.—Reports of the Commissions appointed to examine the Cinghalese Araucarians and Kalmuks who have been brought to the Jardin d'Acclimatation for purposes of ethnographic investigation. The reports on the two latter have been drawn up by M. Deniker, whose intimate acquaintance with the language and homes of the Kalmucks gives special value to his comprehensive exposition of the ethnological and social characteristics of these people.—Recollections of Paul Broca as a student, by M. Eschenauer.—On the "Tzompantli," or sacrificial cranium, exposed in Aztek temples, by M. Hamy.—On the cranial differences observable in men and women, by M. Manouvrier, who considers that while the parietal is less developed in the latter, the occipital is generally larger in women than in men.—On the microscopical characters of the blood in the principal races, by Dr. Maurel, whose investigations do not appear to have demonstrated any very precise ethnic difference in the relations of the red and white corpuscles, unless we may accept as such his observation that the red globules of different races show different degrees of resistance to different artificial reagents.—On the use of iron in Egypt, by M. E. Soldi; and on the use of iron in China, by M. Milloué.—A *résumé*, by M. G. Hervé, of the various medical and other reports of the dimensions of Cuvier's brain. M. Hervé, basing his remarks on Dr. E. Rousseau's report of the autopsy in which the latter took part, gives the weight as 1830 grm., and the horizontal circumference as 60·45 cm. He denies that Cuvier had ever suffered from any malady capable of affect-

ing the size or condition of the brain.—On muscular anomalies of the diaphragm; suggestions for a planispheric representation of the cerebral convolutions, by M. Duval.—On the disappearance of the more fitting in the struggle for existence, by M. Delauny. The author endeavours to show that superior as well as inferior species have disappeared, leaving only the intermediate species; the inferior having succumbed to the superior, while the latter have become extinct through sterility.—On the dog of the Tertiary period in Europe, by M. Zalorowski.—On the value of the information to be deduced from ancient Egyptian paintings by the naturalist, ethnographist, and historian, by M. Piétrement.—On a supernumerary nipple with mammary glands in a young woman, by Dr. Testut.—On the origin of right-handedness in man, by Mme. Clémence Royer.—On the symmetrical character in anomalies in man, and on the influence attributable to atavism in such anomalies, by M. Verrier.—On the geographic distribution of the Opatas, Pimas, &c., with an ethnographic chart of the Basin of the Rio Grande de Santiago, by M. E. T. Hamy.

Bulletin de la Société des Naturalistes de Moscou, 1883, No. 3.—History of the hypothesis of the cosmical waves proposed for explaining the forms of the comets, by Prof. Bredichin (with two plates), being a discussion of M. Schwedoff's hypothesis on this subject; and on some apparent anomalies in the structure of the tails of the comets, by the same (both in French). Prof. Bredichin arrives at the conclusion that, more than ever, he is right in affirming that the theory of repulsive forces is enabled to explain and to predict by means of calculus, not only the whole of the phenomena afforded by the comets and their leading features, but also the slightest details of their structure.—A reply of Dr. Morawitz to General Radoszkowsky's critics with regard to the Russian species of *Bombus* (in German).—On the *Pecten excisus* and *pyxidatus*; note by M. Ant. de Gregorio (in French).—Monopetal plants of Dr. Radde, being a continuation, in German, of Dr. Fred. von Herder's capital description of these plants.—Materials to the fauna of Russian Hemiptera, by W. Yakovleff; three new Russian species of *Odontarsus* and one *Emblethis tenellus* from Northern Persia are described (in Russian).—On the beans of *Abrus precatorius* compared with seeds of other Papilionaceæ, by Col. Tichomirow (in German), with two plates.—On the remains of *Edestus* and other fishes from the Lower Carboniferous of Moscow, by Prof. H. Trautschold (in German); the new species *Cymatodus reclinatus*, *Pœcilodus undatus*, and the new genus *Eucanthus margaritatus*, are described.—On the chief problem of higher geodesy, by Th. Sloudsky (with a plate); a mathematical discussion (in French) of the best means for determining the figure of the earth.—Letters from A. Regel from Central Asia.

Atti della R. Accademia dei Lincei, April 6.—Report on Alfonso di Legge's memoir on the length of the solar diameter, by S. Schiaparelli.—On the compressibility of fluids, and especially of water under temperatures varying from 0° to 99° C., and under pressures of from 1 to 4½ atmospheres, by Stefano Pagliani and Giuseppe Vicentini.—On the symbolic meaning of the Egyptian pyramids, by Dr. Ernesto Schiaparelli.—On the theory and classification of homographics in a linear space to any number of dimensions, by Dr. Corrado Segre.—On the equilibrium of flexible and rigid surfaces, part i., by Vito Volterra.—Remarks on the observations of the solar spots and facules made at the observatory of the Collegio Romano during the first quarter of 1884, by Pietro Tacchini.—On some transformations of orthonitroaniline and orthodiammine, by G. Koerner.—On the action of phtalic anhydride on pyrolignite, by G. L. Ciamician and M. Dennstedt.—On the molybdate of didymium, by Alfonso Cossa.—On the geological constitution of the Maritime Alps, by S. Capellini.—On some psychological difficulties which may be explained by the idea of the infinite, by Francesco Bonatelli.—Some fresh experiments with neurine, by Aliprando Moriggia.

Rendiconti del R. Istituto Lombardo, May 1.—Biographical notice of Prof. Giovanni Polli, part i., by Prof. Gaetano Strambio.—On a problem in mathematical analysis, by Prof. F. Brioschi.—Note on certain variations in the stem and blossom of *Gagea arvensis*, Schult, by Silvio Calloni.—On the struggle for existence between the *Staphylinus olens*, Müll., and the *Lumbricus agricola*, Hoffm., by the same author.—The Court of Cassation in connection with the question whether women should be admitted to the legal profession, by Prof. E. Vidari.—Meteorological observations made at the Brera Observatory, Milan, during the month of April.

Rivista Scientifico-Industriale, April 30.—On certain works required to be carried out in the Island of Ischia, in order, if possible, to prevent the disastrous consequences of future earthquakes, by Prof. Temistocle Zona.—Installation of the electric light in the railway station of Porta Nuova at Turin.—Considerations and suggestions regarding the adoption of earthenware tubes in underground telegraphs, by the engineers R. Fabri and G. A. Romano.—Obituary notice of Quintino Sella, with a list of his scientific writings, by Giuseppe Grattarola.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, May 15.—"On the Influence of Coal-dust in Colliery Explosions, No. V." By W. Galloway. Communicated by R. H. Scott, F.R.S.

At the beginning of the first paper on this subject, which I had the honour of reading before the Fellows of the Royal Society now somewhat more than eight years ago (*Proc. Roy. Soc.*, vol. xxiv. p. 354), I gave a short account of what appeared to me to be a rational mode of explaining the occurrence of all great explosions in dry and dusty collieries; and since then I have had opportunities of studying several remarkable instances of this class of phenomena, with the result that I am now more than ever satisfied with the correctness of the views which I then expressed. It is true, as some subsequent writers, among whom I may name Sir Frederick Abel, F.R.S., have observed, that coal-dust had been previously recognised as a factor in colliery explosions. I think I may safely claim, however, that no earlier author had gone the length of crediting it with the *rôle* of principal agent, and relegating fire-damp to a secondary position.

It is also admitted, I believe, by every one familiar with the subject, that my experiments with mixtures of coal-dust and air containing a small proportion of fire-damp were original. Similar experiments were subsequently made by members of the North of England Institute of Mining and Mechanical Engineers, by a committee of the Chesterfield Institute of Engineers, by Prof. Abel on behalf of the Home Office and the Royal Commission on Accidents in Mines, and by others in this country, by MM. Mallard and Le Chatelier for the Commission du Grisou in France, and by others on the Continent, all of which led to the same conclusion, namely, that air containing too small a proportion of fire-damp to render it inflammable at ordinary pressure and temperature becomes so when coal-dust is added to it. Differences of opinion were expressed as to the actual proportion of fire-damp, the comparative fineness of the coal-dust, and the quality of the coal necessary to the attainment of this result, but the general conclusion, in every case, was the one I have stated above.

In my first paper, already referred to, I had said: "If it could be shown therefore, that a mixture of air and coal-dust is inflammable at ordinary pressure and temperature, there could be no difficulty in accounting for the extent and violence of many explosions which have occurred in mines in which no large accumulations of fire-damp were known to exist," and, immediately following these words, I gave what appears to me to be a new hypothesis regarding the mode of occurrence of great colliery explosions.

My reasons for thinking it necessary to show that a mixture of air and coal-dust alone is inflammable were, first, that after some great explosions it was found that the flame had passed through very long galleries, containing presumably nothing but pure air, and of course dry coal-dust in a state of greater or less purity; and secondly, it was impossible to account for certain other explosions, except on the supposition that they had been originated by the firing of a shot in pure air in galleries containing dry coal-dust as in the last case. To have proved that a mixture of air, coal-dust, and fire-damp is inflammable did not appear to me fully to meet the case, and it was for this reason that I made further experiments with the help of a grant made to me by the Lords of Committee of Council on Education at the recommendation of this Society. The results have been described in some of the former papers of this series. In making these experiments, and in drawing certain conclusions from them, all favourable to the hypothesis referred to, I was simply carrying out the details of the work then begun, and nothing more.

In former papers I referred to several great explosions which had come under my own immediate observation. In particular I had made a very careful and complete examination of Penygraig Colliery after the explosion there in December 1880 (*Proc.*

Roy. Soc., vol. xxxii. p. 454), when I found that the flame had penetrated into every working place in the mine. The plan which accompanies No. III. paper shows that all the working places were ventilated by what was, practically, a single current of air. It was, therefore, open to those who attribute every great explosion to the occurrence of a sudden outburst of fire-damp, and, as the annals of mining show, they constituted a very large majority before the appearance of my first paper on coal-dust, to say that this explosion was due to the same cause. For this reason I have paid particular attention to the phenomena due to the explosion which occurred at Dinas Colliery on January 13, 1879. I do not propose to enter into the minute details of this case, as I should to a large extent simply be repeating what I stated about Penygraig explosion, but will confine myself to those which are necessary or new. I had frequently inspected the workings before the explosion, and I have done so at intervals of one month or less since then, so that I have been intimately acquainted with all the conditions of the mine for many years. I know also that no sudden outburst of fire-damp has ever been known to take place in it. The workings were naturally very dry, the temperature ranging from 75° to 82° F., and the floor was covered with coal-dust. Shot firing was carried on by night when the explosion happened. The damage done by the explosion was very great, the workings being wrecked to such an extent as to lead to their temporary abandonment. They were reopened after a large expenditure of time and labour, and it was only towards the end of last year that I was able to inspect one of the districts of working places, and early in the present year that I could get into the other. With the exception of some burnt hay or dried grass which I found in one of the return air-ways, I saw no traces of burning nor deposits of coked coal-dust in any of the main roadways, but I found well-marked deposits of coked coal dust in all the working places in both districts of workings as far as I was able to penetrate. The plan shows that the current of fresh air which came down the downcast shaft was split up into three separate currents. The two districts were thus ventilated quite independently of each other, and it was therefore impossible for any outburst of fire-damp which might take place in one of them to affect the quality of the air in the other.

We are thus compelled to fall back upon some other mode of explanation in this case, and I now submit that in the present, and in my previous papers, I have brought forward sufficient evidence to show that the coal-dust hypothesis is the only tenable one. If it be admitted, however, that this hypothesis is applicable to Dinas explosion, the conclusion is inevitable that, *cæteris paribus*, it is equally applicable to every case of the same kind that has ever occurred.

Zoological Society, June 3.—Prof. A. Newton, F.R.S., vice-president, in the chair.—A letter was read from Mr. Albert A. C. Le Souëf, C.M.Z.S., of the Zoological Gardens, Melbourne, giving an account of the unusual occurrence of two young ones being produced from one egg laid by a black-necked swan. The writer described the appearance of these cygnets, which were much smaller than a companion bird of the same age.—Mr. F. E. Beddard read a paper upon the visceral anatomy of *Hapalemur griseus*, and called attention to the various points of difference between this species and *Hapalemur simus*.—Mr. A. D. Bartlett read a paper on some singular hybrids of bovine animals bred in the Society's Gardens.—Mr. G. E. Dobson, F.R.S., read a paper on the unimportance of the presence or absence of the hallux as a generic character in Mammalia, as evidenced by the gradual disappearance of this digit within the limits of a single genus (*Erinaceus*).—A communication was read from Mr. H. W. Bates, containing a list of the Coleoptera of the families Carabidæ and Scarabæidæ collected by the late Mr. W. A. Forbes on the Lower Niger. Of these three appeared to be previously undescribed.—Dr. Carl Lumholtz read a paper containing notes upon some mammals which he had recently discovered in Queensland.

Anthropological Institute, May 13.—Prof. Flower, F.R.S., president, in the chair.—Dr. Maxwell T. Masters exhibited a series of agricultural implements brought by Mr. Livesay from the Naga Hills, at the north-east corner of Assam. The tools were chiefly such as are used for rice culture on the irrigated slopes of the hills, and consisted of rakes made of bamboo and wood, a hoe and iron knife with wooden sheath and cord for suspension.—Dr. J. Stephens sent a drawing of a large pointed palæolithic implement recently found near Reading, length 9¼ inches, weight 2 lbs. 3¼ oz.—Mr. W. G. Smith exhibited two palæolithic implements recently found in North London. One was made of quartzite, and is the first example of this material met with in the London gravels; the other was a white implement from the "trail and warp." He also exhibited two white porcellaneous palæolithic flakes replaced on to their original blocks; the four pieces were found by him in North London, wide distances apart, at different times during the last six years. —Mr. Smith also exhibited a large axe from New Guinea with a keen blade of siliceous schist or banded chert, 9⅜ inches long, and weighing over 2¼ lbs. The axe was sent home by a sailor, and Mr. Smith purchased it of a person who was using it in North London for chopping up firewood.—A paper on the ethnology of the Andaman Islands, by Mr. E. H. Man was read.—Prof. Flower read some additional observations on the osteology of the natives of the Andaman Islands. Since reading a paper before the Institute on the same subject in 1879, the author had had the opportunity of examining ten additional skeletons, two of which are in the Museum of the University of Oxford, and eight in the Barnard Davis Collection now in the Museum of the Royal College of Surgeons. Five are males and five females, and all are adult. The measurements of these specimens have thoroughly established the fact that the twelve skulls of each sex previously examined furnished a very fair average of the characters of the race.

CAMBRIDGE

Philosophical Society, April 28.—Mr. Glaisher, president, in the chair.—The following communications were made to the Society:—By Mr. R. T. Glazebrook, on the electro-magnetic theory of light.—By Mr. A. H. Leahy, on the pulsation of spheres in an elastic medium. The problem of two pulsating spheres in an incompressible fluid has been discussed by several writers. The author considers the analogous problem in the case in which the medium surrounding the spheres has the properties of an elastic solid. He finds that the most important term in the expression of the law of force between the two spheres varies inversely as the square of the distance between them. This force will be an attraction if the spheres be in unlike phases, a repulsion if they be in like phases at any instant. The next term in the expression varies inversely as the cube of the distance between the two spheres, and is always a repulsion.

EDINBURGH

Royal Society, June 2.—Sheriff Forbes Irvine in the chair. —Prof. Tait communicated a paper by the Rev. T. P. Kirkman on the enumeration, description, and construction of knots. The paper described the application of a particular set of the polyhedra investigated by the author to the investigation of the subject.—Prof. Tait then read the second part of a former paper of his own on knots. He first considered the modification required to be made on Mr. Kirkman's diagrams so that they might represent actual knots. He also took up the question of the identity of some of the figures with the view of determining the actual number of different knots having a given number of crossings. Finally he recurred to the problem of beknottedness, showing how it was to be determined in any case upon the consideration that *locking* may occur with two strings, and even with one, as well as with three.—Mr. John Aitken read a second note on the recent sunsets, showing how all the phenomena observed received a satisfactory explanation on the hypothesis that they resulted from the presence of abnormal quantities of dust particles in the air. He pointed out that the facts considered adverse to this conclusion really furnished additional proof.—Mr. Aitken then read a paper on thermometer screens, which gave rise to an animated discussion.

DUBLIN

Royal Society, May 19.—Section of Physical and Experimental Science.—G. F. Fitzgerald, F.R.S., in the chair.—On the pitch-curves of cogged wheels, by A. H. Curtis, LL.D. The author showed that a pitch-curve A, *of any form*, its axis a, and also the axis b of the corresponding pitch-curve B, being given, the curve B must be such that, if it roll without sliding on A (the initial point of contact c being of points which in working would come together), carrying b with it, the roulette thus described by b will be a circle having a for centre; hence he deduced the known result that the point of contact of the pitch-curves must be situated on $a\,b$—for the tangent at b to the roulette must be perpendicular to $b\,c$, while, as this roulette is a circle, this tangent must also be perpendicular to $a\,b$; he proved that, if $p = \phi(r)$ be the equation of A, $p' = \frac{r'}{\kappa - r'}\,\phi(\kappa - r')$,

where κ = length $a\ b$, will be the equation of B. He mentioned also that Prof. Willis had proved that *all* working teeth on corresponding pitch-curves are roulettes of the same curve and generated by the same point, and also that, with circular pitch-curves, teeth which were involutes of circles concentric respectively with the corresponding pitch-curves, and having the same centre of similitude with them, would work correctly, and stated that these theorems taken together had suggested to him the question, What curve rolling on a circle will generate, and by what point, the involute of a concentric circle? This curve he proved to be an equilateral spiral whose pole is the generating point.—On the alleged effect of magnetism on the human body, by Prof. W. F. Barrett. In a recent address Sir W. Thomson drew attention to the "marvellous fact" that a powerful magnetic field appeared to exert no action on the human body, and stated his conviction that, "if there is not a distinct magnetic sense, it is a very great wonder that there is not." The object of the present paper was to describe certain facts which had come under the author's observation, and which pointed in the direction of a distinct sensory and therapeutic effect produced by a powerful electro-magnet upon certain individuals. A careful examination of upwards of 100 persons had led to the discovery of three individuals who could instantly detect by their sensations when the current was put on or taken off a large electro-magnet, between the poles of which their heads had been placed. In an absolutely darkened room a singular luminous glare was also seen over the magnetic poles by these three observers. Every care was taken to avoid collusion or chance coincidence, and the observers had no means of knowing by any other means when the current was put "on" or "off." If a distinct magnetic sense exist, as these experiments seem to suggest, it is doubtless rare and fitful, depending possibly on the state of the percipient's health. The author then described experiments that had been made by Charcot in Paris, Dr. W. H. Stone at St. Thomas's Hospital, London, and Prof. Dreschfeld at the Manchester Infirmary, to ascertain the pathological effect of a powerful magnet. The two former authorities had noticed the transference of sensation produced by magnetism in patients suffering from hysteria or hemi-anæsthesia, under conditions which appeared to preclude the possibility of imagination coming into play. Dr. Dreschfeld describes three cases which came under his own observation where anæsthesia was cured by a large electro-magnet. In one case, particulars of which were published in the *British Medical Journal*, every care was taken to eliminate causes other than the specific effect of magnetism, and there seemed no doubt that the patient's complete restoration to health was due to the latter cause alone. In conclusion Prof. Barrett remarked that should the therapeutic value of magnetism in certain specific disorders be established, it would obviously give no support to certain magnetic appliances which are sold as nostrums for all diseases, and of the specific value of which he was not aware that there exists the smallest medical evidence.—On the substitution of sodium bichromate for the potassium salt in bichromate batteries, by Prof. W. F. Barrett. Prof. Barrett stated that a week or two ago Mr. Moss placed in his hands a specimen of bichromate of soda, and asked him to try whether it would efficiently replace the potash salt which is invariably employed in bichromate cells. The result of his examination showed that there was no appreciable difference between the electromotive force, the internal resistance, and the constancy of the two cells, charged with equal weights of the soda and of the potash salt respectively.—Reply to the criticisms of M. Lœwy, by Howard Grubb, F.R.S. (see NATURE for May 29, p. 100).

Section of Natural Science.—V. Ball, F.R.S., in the chair.—On the origin of freshwater faunæ, a study in evolution, by Prof. W. J. Sollas, D.Sc., F.G.S. The poverty of freshwater faunæ as compared with marine is commonly attributed to a supposed inadaptability on the part of marine organisms to existence in fresh water. That this explanation is inadequate is shown by the existence of freshwater jelly-fish such as *Limnocodium*, and still more directly by the experiments of Beudant, who succeeded in accustoming several kinds of marine mollusca to a freshwater habitat. The view of Von Martens that the severity of a freshwater climate is prohibitive of the existence of most marine forms in rivers is insufficient, and a more thoroughgoing explanation is necessary. This is to be found in a study of the means by which the distribution of marine animals is secured. In the case of stationary forms free-swimming embryos are distributed over wide areas by currents, and they can never pass from the sea into rivers, in which the current is always directed seawards. Nor, probably, could an attached form once introduced into a river permanently establish itself so long as its propagation took place exclusively through free-swimming larvæ, for these would gradually be borne out to sea. Hence, freshwater animals should not, as a rule, pass through a free larval stage of existence, nor, as a matter of fact, do they. In Hydra, freshwater sponges, and Polyzoa, the young usually emerge from a horny cyst in the complete state. In the Unionidæ, the glochidium s age provides for distribution without involving a seaward journey. The young of freshwater mollusks do not enter upon a free existence till they are similar to their parents, and Paludina is viviparous. The suppression of a free-swimming larval stage not only occurs in freshwater but in many marine invertebrates. This is connected with the fact that the larval stage is in a position of disadvantage as compared with the adult. Hence there is an advantage to the organism if the larval stage can be passed over in a state of seclusion. From this various other modifications follow; development in seclusion involves a supply of accessible food, hence the appearance of yelk and other kinds of nourishment furnished by the parent to the imprisoned embryo. Again, the secluded larva being spared the drudgery of working for its own existence, and supplied with nutriment in a form that puts the least tax on its digestive powers, a larger balance of energy remains available for metamorphic changes. Thus arise the phenomena of accelerated and abbreviated development. Further, the shortening of the larval life probably leads to the lengthening of the adult life, and shifts the chances of variation and selection forward into the adult stage. Thus animals which hatch out in a complete state will most probably suffer modifications of that state, and not of previous ones, except very indirectly. Here we discover a direct tendency towards a mode of development which explains the "arborescent" character of our zoological classifications, *i.e.* the tendency of the tree of life is now to produce leaves rather than new branches. In the case of freshwater fauna very direct reasons have existed for the suppression of the free larval stage. In this connection may be noticed the richness in species and the poverty in genera of the freshwater mollusca. In discussing the origin of freshwater faunæ there are three hypotheses from which we have to select: (1) that marine forms have migrated into rivers; (2) that they have migrated into marshes and thence into rivers; and (3) that marine areas have been converted into freshwater ones. The last course has been the most usual, especially in the case of non-locomotive forms. Hence the origin of freshwater invertebrates is connected with the great movements which have affected the earth's crust. The earliest well-known lacustrine areas are those of the Old Red Sandstone, in one of which we meet with the earliest known freshwater mollusk, *Anodonta jukesii* (Forbes). The lakes of the Permo-Triassic period contributed additions to the freshwater fauna of the globe. The *Neritidæ* and *Cerithiadæ* are probably post-Palæozoic families, and, as the *Neritina* and *Melaniidæ* are so closely connected with them, they may be regarded as their collateral or direct descendants, and thus may have originated in Triassic lakes, but not earlier. Other genera probably arose at the same time; the occurrence in Cretaceous deposits of *Unio*, *Physa*, *Valvata*, and *Lymnea* in the Nearctic, Palæarctic, and Oriental regions, suggests a high antiquity for these genera; and they may have existed in Palæozoic times. The lakes of the Tertiary period furnished probably further contributions to our freshwater fauna, such as *Lithoglyphus* and *Dreissena*. Thus, existing freshwater genera are probably descended from marine forms which became metamorphosed in the waters of the Devonian, Triassic, and Tertiary lakes. In the lakes of Central Africa the Tertiary freshwater fauna still survives, nearly all of the genera from Lake Tanganyika being referable to genera already in existence in Mesozoic and Tertiary times. The lakes of the Northern Hemisphere received on subsiding beneath the glacial sea such Arctic forms as *Mysis relicta* and *Pontoporeia affinis*, but most of their existing inhabitants have re-entered them since their emergence from the sea.

PARIS

Academy of Sciences, May 26.—M. Rolland, president, in the chair.—Observations of the small planets made with the great meridian instrument of the Paris Observatory during the first three months of the year 1884; communicated by M. Mouchez. The observations of January 11, February 11 and 12, March 14 and 15, were made by M. P. Puiseux, all the rest by M. H. Renan.—Remarks on the sense of sight in its relations with different colours placed in juxtaposition, by M. Chevreul.—Fresh experiments made with a view to determine the locality

and mode of formation of urea in the animal system, by MM. Gréhant and Quinquaud. From these experiments, which consisted mainly in making a quantitative analysis of the urea in the blood flowing to and from a given organ, the authors infer that the abdominal viscera are the seat of a continuous formation of urea.—Experimental studies on the anæsthetic properties of the chlorurretted derivatives of formine, by MM. J. Regnauld and Villejean.—On the theory of quaternions: a demonstration of Sylvester's proposition that the theory of quaternions is identical with the theory of binary matrices, by M. Ed. Weyr.—On the circulation of the liquid mass of the sun, by M. P. Lamey. Assuming as a postulate the total fluidity of the solar mass, the author endeavours to show that, in virtue of the continuous cooling of the surface layer, the whole volume must be in constant circulation, and that the circuit thence resulting may be represented by a simple geometrical figure, which has several points at a tangent with the surface of the solar globe.—Note on the electric conductivity of the liquid and solid anhydrous salts, by M. Foussereau.—On the gaseous tensions of liquid amalgams, by M. Isambert.—Thermic studies of the alkaline fluosilicates: three methods of obtaining fluosilicates of potassa, soda, and lithia, by M. Ch. Truchot.—Fresh researches on bromuretted carbolic acids—their melting heat, specific heat, and heat of neutralisation, by M. E. Werner.—On some reactions of albumen, by M. E. Grimaux.—Analytical study of the chief mineral fertilisers contained in arable lands, by M. G. Lechartier.—Note on the alluvial and lacustrine formations of the basin of the Shott Melrirh, Eastern Sahara, by M. G. Rolland.—On the transformations of a parasitic Peridinian (*Gymnodinium pulvisculus*, Bergh.), by M. G. Pouchet.—A contribution to the study of the virulent principle in puerperal septicæmia, by M. S. Arloing.—On a new method of transfusion of blood previously subjected to the action of peptone, by M. Afanassiew.—On the exaggerated statements regarding the intensity of atmospheric evaporation during the spring equinox, with comparative readings of the evaporometer during the years 1873-1884, by M. L. Descroix.

June 2.—M. Rolland, president, in the chair.—Arithmetical commentary on the theorem discussed by Gauss in his "Disquisitiones," § 357, by M. de Jonquières.—Note on the theory of the winding-gear employed in extracting ores from deep mines, by M. Haton de la Goupillière.—On the mean reciprocal distances of the planets in the primordial state of the solar system; letter addressed to M. Hermite by M. Hugo Gyldén. The respective mean distances, supposed to be far less absolutely than at present, are determined as under:—Mercury, 0·443; Venus, 0·519; Earth, 0·562; Mars, 0·625; Jupiter, 0·850; Saturn, 0·988; Uranus, 1·177; Neptune, 1·322.—Explanation of a method of determining the temperature of the parts of the sun below the photosphere, by M. Hirn.—Fermentation of saccharine juices; experimental researches on the influence of the pneumatic treatment by a current of purified air at the ordinary temperature, or heated to 65° C., by M. P. Calliburcès.—Suggestions for constructing a mercurial galvanometer (hydrostatic galvanometer), by M. J. Carpentier. The paper refers to experiments made as early as January 1881, and are here reproduced as having preceded the apparatus of a similar character submitted to the Academy by M. Lippmann on May 19, 1884.—On the reaction of fused gold and silver in the vapour of phosphorus, by MM. P. Hautefeuille and A. Perrey.—On the action of the sulphuret of mercury on the sulphuret of potassium, by M. A. Ditte.—Note on the combination of chlorides of gold with chlorides of phosphorus by M. L. Lindet.—On the anatomy and nervous system of the Australasian Gasteropod, *Parmophorus australis* (*Scutus*), by M. Boutan.—Contributions to the natural history of the Haliotides, by M. H. Wegmann. The author, who had previously submitted a study of their nervous system, here completes the subject by a full anatomical description of these animals.—Account of the freshwater *Lithoderma fontanum*, Nob., a species of brown Alga (Melanophyceæ) from Montpellier, by M. Ch. Flahault.—On a new genus of vegetable fossils discovered by M. Fayol in the coal-mines of Commentry, by MM. B. Renault and R. Zeiller. The authors, who, from their discoverer, propose the generic name of Fayolia for these plants, give full-size illustrations of two species, *F. dentata* and *F. grandis*.—On some new types of rocks from the volcanic Mount Dore (Clermont), with a description of the successive formations in that district, by M. A. Michel Lévy.—Hydrology of the Ohio Basin, in connection with the recent disastrous inundations in that region, with map, by MM. Fr. Mahan and G. Lemoine.—On the pseudo-meningitis (pseudo-meningitis otopiesis) observed in young deaf-and-dumb subjects, by M. Boucheron.

VIENNA

Imperial Academy of Sciences, May 8.—R. Latzel, on the Myriopoda of the Austro-Hungarian Empire (containing the description of Symphyleæ, Ponropoda, Diplopoda).—K. Deschmann, on the tumuli of Rovisce in the parish of Bründl in Lower Carniola.—L. Boltzmann, on the possibility of basing a kinetic theory of gases on attractive forces alone.—P. Czermak, on the value of some integrals of Maxwell's theory of gases based on a certain law of forces.—F. Zehden, method for calculating a true moon distance by an observed one.—E. Zuckerkandl, on the apparatus of circulation in the nasal mucous membrane.—F. Rimmer, experiments on nutations and directions of growth of seed-plants.—T. Habermann, on diethylalizarin-ether.—F. Fiala, on some mixed ethers of hydroquinone.

May 15.—A. Rollett, contribution to a knowledge of the process of contraction in striated muscles.—F. Kolacek, on a method for determining the electric conductivity of liquids.—A. G. Nathorit, remarks on Herr von Ettingshausen's essay, "On the Tertiary Flora of Japan."—C. Langer, on the origin of the internal jugular vein.—D. Lersch, notes on comets.—E. von Hœrdtl, contributions to Assyrian chronology.

THE LONDON WATER-SUPPLY

The London Water-Supply; its Past, Present, and Future. By G. Phillips Bevan, F.S.S. With a Map showing the Districts of the Water Companies. (London: E. Stanford, 1884.)

THE London water-supply is so important a question, and at the same time one upon which there prevails so much misapprehension, that the appearance of an impartial, candid, and, in the main, accurate treatise like the one before us must be judged seasonable. A full discussion, indeed, of so many-sided and complicated a subject cannot be expected within the compass of 112 pages. Nor is there, perhaps, any man living who is qualified to give an authoritative deliverance on all the considerations involved, —on the one hand, medical, chemical, and engineering, and on the other hand, financial, legal, ethical, and municipal, if not actually political. These two main branches of the inquiry should be kept substantially distinct. For it is at least conceivable that a water-supply might be found irreproachable in quality and ample in quantity, and yet might be furnished on terms so iniquitous as to call for a sweeping reform. Again, a contaminated water might be dealt out in a manner which at least involved no injustice or oppression.

As a matter of course, we shall discuss Mr. Bevan's pamphlet mainly from the sanitary point of view, though we admit that as a whole it well merits the careful study of the ratepayers of the metropolis.

Our author begins with an account of the ancient supply down to the reign of Charles II. This chaper, like history generally, is mainly a record of errors and oversights. It would seem that whilst as individuals we recommend forethought and prudence, yet as a community we very literally "take no thought for the morrow," and thus drift into positions from which we can escape, if at all, only at great cost.

The second chapter deals with the modern supply. It appears that as far back as 1821-28 there was general dissatisfaction both with "the high-handed and arbitrary character of the rates" and with the quality of the water furnished. One company, we learn, took in its supply from the Thames at the mouth of a main sewer, and served out this liquid to its customers without any process of purification. As a specimen of neglect on the part of Government, we may mention that a Royal Commission was appointed to examine the water-supply as far back as 1828. A Select Committee of the House of Commons was still "considering" the report of the Commissioners just six years afterwards, while the Select Committee of the House of Lords took another six years over the matter, and did not consider it until 1840.

Even in those early days attention was drawn to "the filthy and polluted state of the cisterns and butts into which water is received." This nuisance is a necessary consequence of the intermittent system of water-supply. In addition comes the fact that the cistern is generally placed where it is fully exposed to the sun in summer and to the frost in winter.

We find next a history of the cholera epidemics, their bearing on the water-supply question, and the evidence which they yielded as to the influence of sewage pollution. This influence, as worked out by Mr. Simon, is most striking. Among the population of 166,906 persons supplied with a fairly good water by the Lambeth Company in 1854, the deaths from cholera were at the rate of 37 to 10,000 living. Among the 268,171 persons supplied by the Southwark and Vauxhall Company with a polluted water, the death-rate from cholera was 130 per 10,000. Now, as the two companies at that time competed with each other, their "mains branching within the same area, often running parallel in the same streets," this case was a truly crucial instance. The observations thus made proved to be of no small value. The water companies introduced a variety of improvements. The intakes were removed further from sources of pollution, and more efficient arrangements for filtration were adopted. In 1856 Professors Hofmann and Blyth were able to announce that the organic matter in the water supplied was nearly one-half less than it had been in 1851. It is to be regretted, however, that the lesson was over-learnt, and that fanciful and exaggerated notions concerning "contamination" became fashionable. The dogma—for it is not a demonstrated truth—was put forward that all nitrates present in subsoils and rocks result from the decomposition of animal matter. Hence the presence in a water of such salts was deemed a proof that sewage or kindred matters had at some time gained access to the source in question. To this subject, however, we shall have to return below.

An important step has been the closing of the public wells and pumps in and near London. The water of these wells was not merely found to be grossly polluted, but positive proof was obtained that those who drank it suffered exceptionally from cholera. The popularity of these wells may strike us as remarkable. But we must remember that such water cost the consumer nothing. In addition, as Mr. Bevan points out, "the cisterns of the neighbouring houses were generally foul and the water heated, while the well water came up fresh, cool, and sparkling, from the quantity of carbonic acid contained in it."

Mention is made of the establishment in 1868 of a system of inspection of the water supplied to the metropolis. It is not, however, generally known that all the reports issued prior to the investigations undertaken by Mr. Crookes and by Drs. Odling and Meymott Tidy have been based on the analysis of "a single sample of each company's water, taken on one day only in the course of the month." It is plain that such an examination is not alone "rather of a perfunctory nature," as Mr. Bevan says was the case previous to 1865, but positively misleading. We must agree with Messrs. Crookes, Odling, and Tidy that it is "quite impossible to judge fairly the purity or otherwise of a month's supply by an odd sample taken at random in the manner adopted." Hence we are by no means satisfied that the monthly reports issued by Colonel Sir Francis Bolton are of the "immense practical value" which Mr. Bevan seems to believe.

The third chapter is devoted to the existing water companies—their supplies or feeders, reservoirs, and filter-beds; the statistics of the districts supplied, and, above all, their scale of charges. Into these questions, important

as they are, we cannot here enter. We notice merely Mr. Bevan's argument against the compulsory sale of water by meter. He contends that it would "simply result in the greatly decreased use of the water, very much to the detriment of cleanliness and godliness." Surely this hypothetical objection can count for little when weighed against the illogical rating system, which makes a man liable to pay more for his water-supply because his rent and taxes have been raised, *i.e.* because he is poorer! Mr. Bevan, in concluding this chapter, expresses the hope that "either from the operation of purchase, control, or competition, the water question will soon reach a fair and equitable level to both consumer and supplier."

We come now to the main question: Is the existing water-supply satisfactory in quality? and, granting this point, is it not self-evident that, as Mr. Bevan puts it, "it is impossible that the enormous drain upon the Thames can be kept up without its showing signs of exhaustion." The existing supply must, therefore, be supplemented by some new source. Now, in spite of the alarmist speeches, papers, and letters, some of them by authorities of eminence, we still hold that the waters of the Thames and the Lea are not contaminated in such a manner as to render their use inadmissible. It is perfectly true that the country along the Thames and its tributaries above the points where the water companies take in their supplies is inhabited by a large population, whose drainage, not always purified, finds its way ultimately into the river. Now, the late Royal Rivers Pollution Commission, upon what to us seems very scanty evidence, committed itself to the dogma that, "if a river was once polluted with sewage matter, the water of that river was for ever unfit for dietetic purposes, and no practical distance of flow would render such a river safe."

On the other hand, the Royal Commission on Water-Supply (1869) declare in their report (§ 180) that "the organic compounds dissolved in water appear to be of very unstable constitution and to be very easily decomposed, the great agent in their decomposition being oxygen, and the process being considerably hastened by the motion of the water. This purifying process is not a mere theoretical speculation; we have abundant practical evidence of its real action on the Thames and other rivers."

Further (§ 193), "These analyses of Thames waters made for the Commission (by Drs. Frankland and Odling jointly) are sufficient to show, not only the absence of any increase of objectionable matter in the river from Lechlade to Hampton, but that the variations in quality which commence at Lechlade, after showing several temporary changes in many parts of the river's course, fall at Hampton in general to a point as low as at Lechlade (110 miles up stream), and in one respect, viz., the organic nitrogen, *to a point even lower.*"

One more extract may be permitted (§ 214): "Having carefully considered all the information we have been able to collect, we see no evidence to lead us to believe that the water now supplied by the companies is not generally good and wholesome."

It may be urged that these conclusions being based upon evidence obtained in 1869 may not be strictly applicable at the present day. To this the reply is very simple: the results obtained by Messrs. Crookes, Odling, and Tidy in 1881 and subsequently "are in complete agreement with those of the Commission on Water-Supply." Further, certain improvements have since been effected which must lessen the contamination of the Thames above Hampton. We need merely refer in passing to the corroboration which the views of the Water Supply Commission have received from the recent analyses and observations of Dr. F. Hulwa on the Oder at Breslau, of Prof. Leeds on the Brandywine and Passiac Rivers at Paterson, Jersey City, and Newark, or of Delalande on the Vesle at Rheims. All these chemists agree that, since rivers have a self-purifying power, this power, if not interfered with by the continuous introduction of pollution along their course, restores them, not indeed to absolute purity, but to a condition fit for all practical purposes. The public are apt to forget that pure water is a mere abstraction, like the lines and points of the mathematician. It has no existence in nature, and were it procurable might prove ill-adapted for domestic and dietetic purposes.

Taking all that has been said into consideration, we think that all judicious men will be slow to abandon the present supplies of water. There is one especial reason against such a change, which, though not of a sanitary nature, cannot in these days be left out of sight. In such a vital matter London must not make itself dependent upon any one source. Let us for a moment suppose that the alarmist succeeds in prevailing upon us to abandon the Thames, the Lea, and the other gathering-grounds in the neighbourhood of London, and that our entire supply is conveyed from Wales or Cumberland by a gigantic aqueduct. Would it be possible to guard all points of such a line, so as to be safe against the outrages which seem now the order of the day? A quantity of nitro-glycerine, which a man might carry in a carpet-bag without exciting suspicion, would suffice, if skilfully applied, to cause a breach in some part of the structure. And then? How long it might take to make good such a rupture we cannot estimate. In a railway accident, materials, tools, and workmen can be run along the line to the spot where they are required. An aqueduct would present no such facilities. It may be said that a reservoir might be constructed at the London end of the line of sufficient size to tide us over such a possible calamity, but the size and strength of such a store-tank would have to be enormous, and this in itself would present another element of danger.

But whilst it might thus be perilous to supersede the present supply, an addition to our resources will ultimately become needful. Of course, with Mr. Bevan, we can only hope that the additional supply will be the best procurable. But the author here reminds us that, "however pure may be the water at the outset, no power on earth can prevent careless, wilful, or accidental pollution in some part of its long course." In fact, experience tells us that no water-course, exposed to the air for any distance, will contain less than about 0·06 to 0·07 parts of "albuminoid ammonia" per million. The excellent waters of Manchester and Glasgow—the former collected on the barren and unpeopled moorlands of North Derbyshire, and the latter drawn from Loch Katrine—contain this proportion, and the New River water shows no more! It is, therefore, quite an open question what we should gain by going so far afield.

There is another very grave consideration: the soft

waters with which not a few towns in the North of England are supplied, act upon the leaden service-pipes to such an extent as to become dangerous. It may even be questioned whether an occasional epidemic of fever is not a smaller evil than the continued occurrence of lead-poisoning. The use of iron service-pipes, or of lead thickly lined with tin, is troublesome and expensive. Perhaps sooner or later some unobjectionable material may be found to take the place of lead in the manufacture of water-piping.

A well-known authority on water analysis reminds us that waters from the mountains of Wales, Cumberland, &c., may possibly hold lead and copper in solution, and one has been found to contain appreciable quantities of arsenic. Great care would therefore be necessary in the selection of a supply from such districts.

The hardness of the New River water, of that furnished by the Kent Company, and indeed of the London water-supply in general, has often been complained of, and the softness of the northern waters has been urged in their favour. It is, however, by no means certain that from a sanitary point of view a soft water deserves the preference. Many medical authorities contend that a water of moderate hardness is preferable, for dietetic consumption, to such waters as are supplied to Huddersfield, Leeds, Manchester, &c. It is urged, not without a show of probability, that a supply of calcareous salts in drinking-water is especially advantageous in the formation of the bones of young children. Dr. C. Cameron of Dublin, however, maintains that there has been an improvement in the public health of Dublin since the soft water of the Vartry was substituted for the hard water with which that city was formerly supplied. Further inquiry, therefore, is necessary in this direction. It seems to us, however, that there is hardness and hardness. The hardness of water may be due to lime salts or to magnesian compounds. For the latter there is comparatively little need in the human system, and their regular ingestion is found unfavourable to health. But to condemn any water as prejudicial merely on the ground of hardness seems to us rash in the extreme, in view of the high standard of health existing in districts where hard waters only are available.

It has been proposed to increase the London supply by means of a system of artesian wells. Unfortunately, though a single such well may yield a large and continuous supply of water, this quantity cannot be multiplied by sinking similar wells in the neighbourhood, as has been found in the case of the celebrated well of Grenelle. Among the many schemes enumerated by Mr. Bevan, there is one prominent in its singularity. Shafts were to be sunk down to the chalk on each side of the Thames every quarter of a mile. Each such shaft was to have a canal communication with the river between high and low water mark, through which these shafts were to be filled with water. At some distance from each descending shaft another was to be sunk, into which the filtered water would flow as in an inverted siphon, until it rose to the level of the river. The water of deep wells is in general remarkable for its freedom from organic pollution. But this purity probably depends on the slowness of the filtration by which they are supplied.

Our author, after giving the details of a great number of projects, comes to no decided conclusion. He remarks that one of them will ultimately be adopted for the very good reason that a change of some kind will eventually be necessary. But he judiciously adds, "It need not be looked upon as in any way superseding the arrangements of the present supply."

FLOWERS AND THEIR PEDIGREES

Flowers and their Pedigrees. By Grant Allen. (London: Longmans, Green, and Co., 1883.)

THIS book consists of eight short essays on the evolution and distribution of plants which originally appeared as articles in several of the London magazines, supplemented with an introductory chapter. Two of these essays treat of the reasons for the presence of certain plants in our insular flora, as illustrated by the Hairy Spurge (*Euphorbia pilosa*, L.) and the Mountain Tulip (*Lloydia serotina*, Rchb.). The remainder discuss the evolution of certain types of plants, the examples taken being the daisy, strawberries, cleavers, wheat, the family of Rosaceæ, and the cuckoo-pint. The articles are written in the author's well-known pleasant style, and cannot fail to attract and interest many who have never previously turned their attention to the study of our common weeds.

Mr. Grant Allen has a great horror of a "microscopical critic," which he defines as "a learned and tedious person who goes about the world proclaiming to everybody that you don't know something because you don't happen to mention it." After reading this book, however, one feels tempted to reassure him on this head. For the work contains a considerable number of things which we may venture to state nobody ever knew before. Take, for instance, the text of the fifth essay, that on the origin of wheat: "Wheat ranks by descent as a degenerate and degraded lily"; and again, "While the daisy has gone constantly up and while the goose-grass has fallen but a little after a long course of upward development, the grasses generally have from the very first exhibited a constant and unbroken structural decline." This, we think, will be an entirely new view to the botanical morphologist. On these lines he proceeds to trace the evolution of the wheat-plant, from an imaginary primitive Monocotyledon, and suggests that *Alisma ranunculoides* might represent the earliest petal-bearing type in this line of development, except for the fact that its petals are pinky-white instead of yellow! From this plant he traces the descent of the wind-fertilised rushes, the stamens of which he states hang out pensile to the breeze on long slender filaments. This is certainly not the case: the filaments of the rushes are short and rather broad, and the anthers are usually fixed by the base, and not at all more adapted for wind-fertilisation than those of such a plant as the bog-asphodel, which is regularly fertilised by insects.

From the rushes both the sedges and grasses are derived, but on different diverging lines. The former class of plants Mr. Grant Allen considers to be very degenerate in type, the calyx and petals, which were brightly coloured in the lilies, being reduced to the six small dry bristles which we find in some species of Scirpus. He does not explain, however, how it is that some Cyperaceous plants possess seven or eight of these bristles. But the most extraordinary suggestion is that

the female flower of a Carex is represented by "a single ovary inclosed in a loose bag, which may perhaps be the final rudiment of a tubular bell-shaped corolla like that of a hyacinth"! Surely the nature of the utricle of a Carex has been clearly enough demonstrated by the structure of the flowers of monstrous specimens and of allied genera. To complete his remarks upon the sedges he adds a footnote, in which he says: "The sedges are not in all probability a real natural family, but are a group of heterogeneous degraded lilies, containing almost all those kinds in which the reduced florets are covered by a single conspicuous glume-like bract." Now there is probably hardly any large order in the vegetable kingdom so natural as that of the Cyperaceæ, so little connected with any other, and of which the genera are so closely allied together, as is proved by the comparatively small number of genera in it, and the large number of species which many of the genera contain.

The wheat plant being a degraded lily, it becomes necessary to trace the development of the flower of the one into that of the other, which is done by considering the palea of the wheat-flower as homologous with the calyx, and the lodicules as representing the corolla, a view which has long been considered untenable.

The two essays upon the distribution of plants call for some comment. Here the author is on firmer ground, for, thanks to the researches of Forbes and Watson, we have a much clearer notion of the origin of our flora than we can have of the pedigrees of the plants themselves. At the same time we must take exception to the suggestion that the seeds of the northern Holy Grass, which Robert Dick discovered in Caithness, were introduced into New Zealand from Siberia upon the feet of a belated bird. The plant in question does not occur, as far as is known, in New Zealand. The species which does occur both in New Zealand and Europe is found throughout the temperate Antarctic zone, extending even to the Cape. Nor is this distribution, as the author states, a very rare and almost unparalleled coincidence. The fact is that there is a very considerable number of plants common to the north and south temperate regions, most of which occur in North America, and seem to have descended towards the Antarctic regions along the line of the Andes.

But, apart from improbabilities in theory, there are numerous statements which cannot fail to convey erroneous impressions of plant-physiology. What, for instance, could be more misleading than the following statement concerning Potentillas? Those "which raised their leaves highest would best survive, while those which trailed or kept closely along the ground *would soon be starved out for want of carbonic acid!*" It is not the absence of carbonic acid gas that the plant would suffer from, but from the loss of light by which it could utilise it. These statements, and many others of a similar nature, suggest that Mr. Grant Allen has confined his observations too much to the flora of the British Islands. It is utterly impossible to form any correct idea of the history of the evolution of a plant without knowing thoroughly the structure of all the plants in any way related to it, and without having, moreover, a much clearer knowledge of the effects produced by external circumstances in modifying organs than we at present possess. In the meantime dogmatic statements concerning the evolution of any given plant are in the highest degree unsatisfactory, and likely to lead to error.

The book is nicely got up, and the language is in that easy and fluent style in which Mr. Allen is so proficient, and which goes so far towards investing the driest details of science with a poetical and even romantic interest.

H. N. R.

OUR BOOK SHELF

Wonders of Plant-Life. By Sophie Bledsoe Herrick. (London: W. H. Allen and Co., 1884.)

THIS is another well-intentioned but unsuccessful attempt to deal in a popular style with some of the more sensational parts of the science of botany. Inaccuracy is again the glaring fault: thus we read on p. 4 that "vegetable cells, in the earlier stages of development, generally approximate to the sphere in form"; on p. 17 that the vessels "serve to convey air through the tissues of the plant," and "are the lungs of the plant"; and again, on p. 24, that the red and ultra-red rays are those actively concerned in the process of assimilation. Similar inaccuracy may be traced in those of the illustrations which are original; for example, the drawing of Penicillium on p. 60. The frequent production of popular treatises shows that there must be some demand for such books. It is much to be desired that some botanist who is really master of his subject would take the matter up, and write in a popular style a trustworthy account of those parts of the science of botany which are of especial interest to the general public.

Histological Notes for the Use of Medical Students. By W. Horscraft Waters, M.A. (London: Smith, Elder, and Co., 1884.)

IN the introduction to this little work of 65 pages Mr. Waters states that, in taking the class of Practical Histology at the Owens College Medical School during the summer sessions of 1882-83, it had been his custom to give each student "sheets" containing a short account of the chief points to be observed in the specimens for examination. The present work has grown out of these notes, after careful revision and additions thereto by the author. Students of histology have already numerous similar treatises placed at their disposition, describing the various methods of staining, clearing, and mounting specimens; but room will always be found for additional ones bearing on this subject, provided they are the outcome of practical experience. These notes have been carefully prepared; the directions given are clear and concise, and beginners cannot do better than carefully follow them.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Pile-Dwellings on Hill-tops

I OBSERVE this question to the fore in NATURE of February 21 (p. 382), and as I have lived many years among races who build various forms of pile-houses, and have often resided in them for a time, I trust you can allow me a few words on the subject. The custom seems attributed to several causes, *i.e.* to excessive moisture and as a protection against wild beasts, by Mr. Keane; to excessive rain and a wet climate, by Col. Godwin-Austen; to damp exhalations from tropical soil, by Mr. Dallas; and to the

survival of a purposeful habit of building over water, by Mr. Tylor.

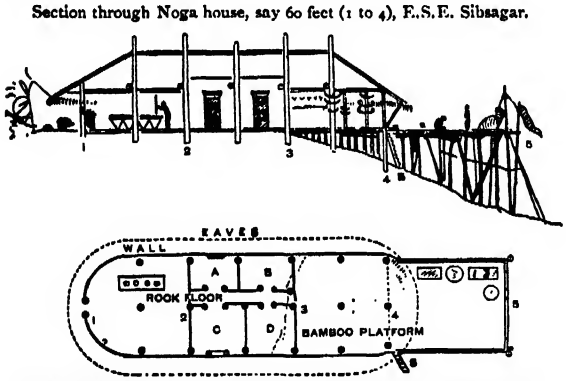
A considerable experience among Nogas, Miris, Singphus, Kamtis, Deodhains, and Duonias, who all build pile-houses a little varied in kind, convinces me that the above reasons are not strictly correct.

Possibly the Swiss lake-dwellers descended from Eastern races who built over water, and inherited a custom that perhaps subsequently proved to be beneficial to them when and where large Carnivora were common. As regards India, it seems to me there are good reasons for believing these pile-builders are the direct descendants of the pre-Aryan aboriginals, and if they brought the custom with them from the south, it must be of extreme antiquity, and have developed adaptations to local needs, as it is not here used over water.

It seems hardly due to moisture and tropical rains, as the Kasias, Augamis, and Garos, who live in the wettest climate of all, build on the ground. Again, among those who build on piles many live and sleep on the ground, using the piled part of the house for other purposes. The platforms also are generally too low to afford safety from tigers, and if so needful for health, why is the custom not more general?

Among the Miris, Singphus, Kamtis, Nogas, Mismis, and Deodhains that I have questioned as to the origin of the custom of building on piles, the answer is invariably that they do not know, that it is their tribal custom, &c. Pressed as to the advantages of it, or why they could not build on the ground like Hindus, they generally end by urging the absolute necessity of keeping things out of reach of the ever-present pig.

Section through Noga house, say 60 feet (1 to 4), E.S.E. Sibsagar.



1 to 2, Rice husking; 2 to 3, Sleeping, cooking; 3 to 4, Audience, &c. 5, "Chang" outside; S, Steps up; A B C D, Sleeping-rooms.

Among many of these tribes, where stone for walls is not easily procurable, the jums even have to be at some distance *for the same reason.*

As an illustration of how this animal practically affects the question of house-building, I append a section of a typical average Noga house, as built by the tribes south-east of Sibsagar to the Upper Dihing. One end generally rests on the ground, while the other overhangs a slope for which there often seems to be no occasion, as plenty of level land is about. In all houses of this type the end devoted to husking rice rests on the ground, and the door at that end has a slab that can be raised to admit pigs to eat the husks. This compartment (one-third of the house) is divided from the living and sleeping part by a wall and a door with a stile to keep out pigs. There are generally from two to six, or more, sleeping-rooms on the ground, and beyond them again is an open room used for visitors, or to sit and work in during wet weather. It is hung round with horns and trophies, contains hunting and fishing gear, arms and utensils, and small stores. It is the recognised audience-hall, and built on piles; the floor of it is generally carried out beyond the eaves of the roof, often supported on long bamboos (where the slope is steep), and this outer part or raised floor is seen in some shape or other in all these houses. It is used to sit out on in fine weather, to work on; rice, yams, sliced vegetables, fruit, fish, flesh, &c., are put there to dry; pottery is made, and things laid while they are gone to the jums, safe from the prowling pig. From one end of the house to the other, indeed, these pig scavengers are apparent as an institution.

As a rule these pile-houses run from thirty to two hundred feet long, and are wholly on piles if in the level plains, but the several tribes have slight modifications. They are still built by the Deodhains, a remnant of the Shans who came into Assam in 1228, and gave it their name (from Ahom); about five hundred of these people still remain in some six or eight villages not far off, though dying out. Their language and written character possibly is a unique case of a written language not yet secured. While they remain Ahoms they keep and eat the pig and build on piles, but when converted to Hinduism the pig and piles are given up together.

I am aware that pigs are kept by Kasias and Garos, &c., who yet do not build on piles, but stone for walls and slabs of gneiss are there *alone* common, and are effectually used as inclosures or as barriers. There is practically no building-stone where we see the piles in use; and also bamboo is there common.

But there are many other things besides pile-dwellings that prove these now distinct tribes to have descended from a common stock. The "morongs," or houses in which the lads and single men sleep at night, away from their parents' houses, are seen under various names all through these hills, north, south, and east of Assam, a custom that has survived the differentiation of the languages. There are also "morongs" for the girls and single young women, and there are special and peculiar laws relating to morongs.

Liberty of the sexes before marriage is indeed practically so complete among all these tribes that really *morals begin with marriage.* After marriage they are better, I think, than civilised nations.

These customs and pile-buildings, &c., indicate a common origin, but there are also means by which we can ascertain the common *home* more or less accurately, and which show that these pile-builders are descended from the pre-Aryans of the plains, from Assam to the Indus, who named so many of the rivers. In and around Assam we find these names often begin and end with Di and Ti—as Dihing, Dihong, Dibong, Dibru, Dima, Dipha; Timu, Tiok, Tisa, Tiru, Tiwa, Tista, or Aiti, Galti, Seti, Tapti, Rapti, Kamti, Gulmthi, Ningthi, Lathi, &c. This Di, Ti, means in all cases "water,"—as Ti, water; Sa, the little, young = Tisa, the "young river"; and there are other forms—as Lushai Tui, Kachari Doi, Noga Ti, Tsi, Tzu; Chu is also Thibetan, Bhotan, and Chinee; Mongolian being Su, Ussu.

But the Himalaya has acted as a conspicuous speech-parting. South of it we have the pile-builders' form—Di, Ti, Doi, Da, Dzu; and north of it, from the east of China, all across Central Asia, Persia, and Asia Minor, to the Gulf of Salonica even, we have the northern Chu and Su in some form. Of Kara Su = black water, and Ak Su = white water (our Oxus) there are scores of instances; even the "Ind-us" and Eu-phrat-es, and many others, fall into the group.[1]

I drew up lists of these river-names some years ago in the *Journal A. S. Bengal*, vol. xlviii. part 1, 1879, pp. 258–70.

Thus it would seem as though the races who now build these pile-houses, often on hill-tops, are the descendants of those who named so many of the Indian rivers south of the Himalaya, *i.e.* the pre-Aryan inhabitants.

Whether these races originally came from the south or not we cannot yet be certain. But there are several customs, such as "head-hunting" and "pile-dwelling," held in common with races of the Archipelago; and among the most eastern Nogas the dress is as nearly as possible *identical* with that of the Dyaks, as illustrated in Dr. E. B. Tylor's "Anthropology," so that eventually it may be possible to say.

In conclusion, I might mention that the word "Naga," as applied to the tribes south and south-east of Assam, is an Anglo-Bengali-ism, and misleading. It should be Noga, which is the name by which these tribes are known in Assam. It is not a racial name in the hills at all, and has originated from the Noga word "Nok" for folk.

Thus, Who are you? is "tem nok?" or "o nok e?" N and L are interchangeable letters, and thus Dr. Rajendralala, Mitr, pointed out to me that the Noga Nok and the Sanskrit Lok = man, seem the same word. We use the word Log = folk (logue) almost hourly in Assamese, Bengali, and Hindi, and philologists may perhaps be able to say if we get our word folk from this same root, and for which it is the exact equivalent. But the word for these hill-men is "Noga," and they do *not* worship snakes. The real Nagas are in another part of

[1] The Assyrian hu, Greek eu, Scythian ku = water (A. Cunningham "Anct. Geo.," p. 37).

India, and I trust Dr. Hunter and Mr. Phil Robinson will excuse my saying they are both wrong *re* this name.

These hill-men have histories, if we could only get at them. This I find by having traced forty-six villages (now nine or ten different clans) as being offshoots of "Sang-nu," east-south-east of Sibsagar. Twenty-five generations ago they began to spread. S. E. PEAL

Sibsagar, Assam, May 5

Atmospheric Dust

ON Thursday, April 24, showers of discoloured rain fell at Inglewood, Sandhurst, Castlemaine, Kyneton, Daylesford, and the districts adjacent, that is to say, over an area of more than 2,500 square miles in extent. The heaviest showers—called by all who were out in them "showers of mud"—occurred at 7 o'clock p.m. and near midnight. The leaves of trees and shrubs, roofs of buildings, fences, and everything on which it could rest were more or less covered with red mud. The weather at Sandhurst for some ten days prior to this occurrence had been dry, and for a long period there had been a drought in New South Wales and in many parts northward. At several places in Victoria and New South Wales violent dust-storms occurred on the morning of the 24th immediately preceding the commencement of the rain. Some of the mud, of a bronze colour, collected by Mr. Edward Hurst of Sandhurst, was found by microscopical and chemical examination to be composed of quartz, oxide of iron, and mica; some taken from the rain-gauge stand at the School of Mines was, when dried, an almost impalpable powder of a pale reddish chocolate colour. It was seen to consist of ferruginous quartz and minute particles of black oxide of iron; and a smaller quantity collected at my private meteorological observatory—about three-quarters of a mile distant—was paler in colour, and consisted of quartz (much of it iron-free), alumina, sesquioxide of iron, and white and reddish-yellow mica. A small proportion of it was attractable by the magnet. The water collected in the rain-gauges when agitated was reddish-brown in colour, and the proportion of sediment was very large, leaving no room for doubt that the dust was brought down by the rain. Its composition and the times at which it fell lead me to believe that it came from the north and had travelled far.

The "Red Glow" after Sunset

BEING out on Sandymount Strand last night, whence the western sky may be well observed, I noticed, about 8.45 p.m., the "red glow" over the yellowish sky where the sun had set. It was quite as distinct as during certain evenings at the end of last year. J. P. O'REILLY

Royal College of Science for Ireland, Stephen's Green, Dublin, June 12

The Earthquake

As communications on this subject are still being received by NATURE, and as the records for London and its immediate vicinity have been few, it occurs to me to note the following facts:—At the time of the earthquake I was sitting in my study here. There are several heavy insect-cabinets in the room, and a loud "groan" proceeded from one or more of them, indicating "settling" from some cause or other. Furthermore, the door of the room would not lock on the evening of that day, although the lock had moved freely down to then. And a clock in a bed-room was found to have stopped without any apparent cause at the hour indicated for the earthquake; but as the discovery was not made until late in the evening, it was not possible to decide whether the stoppage had occurred in the morning or evening. As no sensation was *felt*, these matters would have held no significance had it not been for the news in the evening papers of that day. R. McLACHLAN

Clarendon Road, Lewisham, S.E., June 13

Intelligence in Animals

THERE is at Walham Green a daily illustration of intelligence in a donkey which may interest those of your readers who collect such facts. Old Bob the waterman has been known for so many years that it is impossible to say how many. He is one of the few surviving carriers who take round for sale water in a tub on wheels, which is drawn by a donkey. Bob, the tub, and the donkey are one of the institutions of Walham Green. Years ago Bob used to guide his donkey to the pump near the church and then drive him round to his customers. How long the donkey was learning his rounds I do not know. Three years ago Bob used one shaft as a sort of movable crutch, and seemed to trust much to his donkey to go the right way. Now he appears quite blind, for a few days ago he was noticed going into the yard where the pump stands, when the donkey stopped. He asked a boy what his donkey had stopped for, and was told that a cart was in the way. It is interesting to note that the donkey conducts by his own intelligence all the business of water distributor, while Bob has sunk to the condition of mere pumper and of money collector attached to and led by the shafts, which latter duty might be done by an intelligent dog. M.

ADOLPHE WURTZ AND HIS CHEMICAL WORK

BY the death of Adolphe Wurtz on May 12 last, the world, and especially the scientific world, has lost one of its brightest and most energetic leaders,—a successful leader indeed, through perhaps the most difficult period of chemical history—the earliest years of the development of our "modern chemistry." His loss is felt all the more acutely, coming as it does so suddenly and so close upon that of his master and friend, Dumas, whose mantle had fallen upon him.

Charles Adolphe Wurtz was the son of a Protestant clergyman, and was born on November 26, 1817, at Wolfsheim, near Strasburg. He studied in the University of Strasburg in the Medical Faculty, in which he took the Doctor's degree with honours in 1843. He came to Paris in 1844, where he soon attracted the attention of Dumas, and after occupying several positions successively at the École Centrale and the Faculty of Medicine he became Professor at the Institute Agronomique of Versailles, and in 1853 succeeded to the duties of Dumas and Orfila as Professor at the Faculté de Médecine.

Wurtz united in himself all the better qualities of the Gallic and Teutonic character, in his activity of mind and untiring perseverance in the search for truth. He was elected a member of the Academy of Medicine in 1856, and in 1865 was awarded the prize of 20,000 francs for his chemical researches. He became Dean of the Faculty in 1866, and Professor at the Sorbonne in 1878, in which year also he gave the Faraday Lecture at the Royal Institution; the subject of which was the condensation of gases, and his hearers on that occasion will not readily lose the impression of his earnestness and vivacity, especially on the appearance of the liquefied gas (ammonia), and his exclamation, "Voilà! voilà le liquide," &c.

His earnestness of purpose, conjoined with a most genial manner and expression, gave him very great influence over those students who worked with him; and a long list of names might be given of students who have done good service to the science under his guidance and encouragement.

But he not only encouraged the students who came to learn under him, but strove to spread a knowledge of science amongst the mass of the public, in which task he was eminently successful.

In addition to his onerous duties as professor, Wurtz was in 1881 elected permanent Senator, and rendered most valuable services to his country as recorded in his Reports of Commissions on the trichinosis outbreak and on scientific education.

While there are chemists the work and example of Adolphe Wurtz will serve as a beacon and guiding light to still wider and more important facts in our science.

The Royal Society's Catalogue of Scientific Papers contains a list of no fewer than one hundred and four papers to which the name "Adolphe Wurtz" is alone

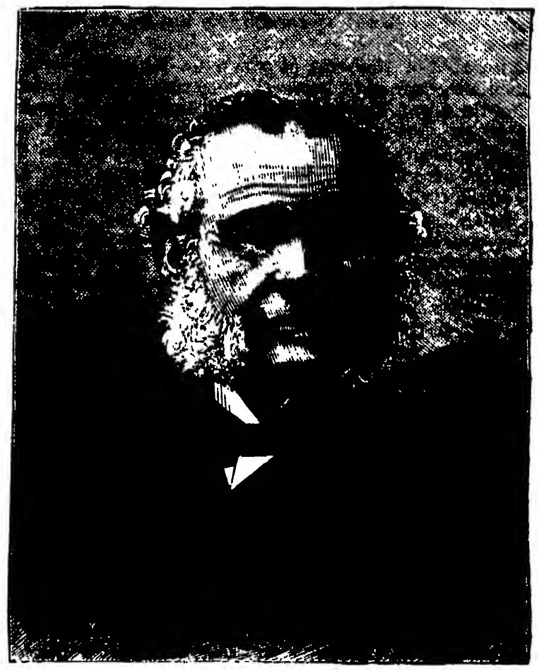
attached; of these a large proportion recite particulars of researches which have furnished results of high theoretical importance, and which entitle their author to be reckoned as one of the chief contributors to the foundation of systematic chemistry. In him French chemists lose their chief leader; but their loss is also that of the scientific world at large. His logical clearness of thought, his breadth of view, and the precision of his statements secured Wurtz an influence wherever chemistry was taught; and at the present time, overwhelmed as we are in the chaos of facts brought to light with such astounding rapidity by the labours of chemists in all parts of the world, the loss of such a master-mind, of a man possessed in so high a degree of the power of coordination, is indeed grievous. His "Introduction to Chemical Philosophy," his "History of Chemical Theory," and his "Atomic Theory," of all of which English translations have been published, afford striking illustrations of the character of his teaching, and are unsurpassed as introductions to the study of the historical development of our science.

Wurtz's first paper, published in 1842, was "On the Constitution of the Hypophosphites," and, together with another on the same subject put forward a year or so later, forms not the least important of his contributions. Hypophosphorous acid had been discovered by Dulong and afterwards examined by Heinrich Rose, but their results were not in accordance; Wurtz therefore undertook the study of the acid. He established its composition and prepared and analysed a large number of its salts, and was thereby led to the conclusion that hypophosphorous acid contained two atoms of hydrogen which could not be displaced by metals, being, in fact, a monobasic acid; he also showed that of the three atoms of hydrogen in phosphorous acid only two were displaced in the formation of salts. This research was carried out in Dumas' laboratory; it may even now serve as a model of what such work should be.

In the course of his study of the hypophosphites, Wurtz was led to make what probably was his most interesting, although not his most important, discovery: that of copper hydride, Cu_2H_2. Even at the present day, although we have reason to believe that the alkali metals and palladium and platinum form compounds with hydrogen, copper hydride is the only hydride of a metal with which we are acquainted which has anything like definite and specific properties. It is obtained by acting on copper sulphate with hypophosphorous acid as a yellow or reddish-brown precipitate, which when heated readily decomposes into hydrogen and copper, and on treatment with muriatic acid yields cuprous chloride and twice the volume of hydrogen which is obtained on merely heating it. This reaction, as Brodie first pointed out, affords an almost conclusive argument for assuming that the hydrogen molecule is compound in its nature. Berthelot having called in question the existence of cuprous hydride, Wurtz in 1880 maintained the correctness of his original statements. It is to be hoped that this remarkable compound will ere long again attract attention, as it is more than probable that it will be of service as a reducing agent; its thermo-chemical investigation may be expected to furnish important information on the affinity of hydrogen atoms for hydrogen atoms: indeed it is remarkable that it has so long escaped attention from this point of view.

Wurtz paid much attention to the investigation of the cyanogen compounds, and in studying the cyanic ethers was led in 1847-49 to make the most brilliant of his discoveries, that of the compound ammonias. These bodies were obtained by the action of alkali on cyanic ethers, just as ammonia is formed from cyanic acid. In properties they were the precise analogues of ammonia, and on this account, and on account of the manner in which they were produced, Wurtz at once regarded them as ammonias in which an atom of hydrogen is displaced by an alcohol radicle such as methyl or ethyl, thus giving rise to the idea of the ammonia type. Hofmann's discovery, a few months later, of diethylamine and triethylamine, compounds resulting from the displacement of two and three atoms of hydrogen in ammonia by ethyl, and of the method of preparing amines by the action of the alcoholic iodides on ammonia, was a fitting corollary to that of Wurtz. The combined result of these two classical researches was that chemists have ever since accounted for the properties of the organic bases generally by regarding them as derivatives of ammonia, which they all so closely resemble in chemical behaviour.

Passing over numerous investigations of minor value, we come to a paper published in 1855, "On Simple and Mixed Organic Radicles," which at that time was of great importance, and well illustrates Wurtz's method of almost invariably choosing subjects the investigation of which was of special interest as bearing on the advance of chemical theory. This paper is also memorable as con-



ADOLPHE WURTZ (from *La Nature*).

taining the first description of the method now so commonly employed of preparing hydrocarbons by the action of sodium on the iodides and bromides of alcohol radicles, a method which some years afterwards was applied with such success by Fittig in elucidating the constitution of the homologues of benzene. Frankland and Kolbe had maintained that the hydrocarbons of the empirical composition of the so-called alcohol radicles which they had prepared were of the same composition in the free state as in combination: for example, that the hydrocarbon obtained from ethyl iodide, C_2H_5I, was free ethyl, C_2H_5. Gerhardt, Hofmann, Laurent, Brodie, and Wurtz, however, sought to show that they should be represented by a doubled formula: that the so-called ethyl, for instance, had the composition $C_4H_{10} = 2C_2H_5$. This Frankland strenuously opposed, mainly on the ground of the complete homology of the hydrocarbons in question with hydrogen, the formula of which was then almost universally written H. The arguments used were chiefly of a physical character. Wurtz put an end to the controversy

by introducing an argument which at once appealed to the sympathy of the chemist, by showing that, if a mixture of the iodides of two distinct radicles, such as ethyl, C_2H_5, and butyl, C_4H_9, were submitted to the action of sodium, a hydrocarbon was produced which consisted of ethyl and butyl united together. There was no reason to suppose that when a single iodide was thus treated the radicle remained free, and Wurtz showed that the physical properties of the hydrocarbons produced from single iodides were such as to prove that they were formed by the union of two similar radicles, as on no other hypothesis could they be ranged in a series with the hydrocarbons resulting from the association of two dissimilar radicles. It was a logical extension of this discovery to double the formula of free hydrogen, a step which, indeed, Brodie had already advocated, and which Frankland had clearly maintained was an essential preliminary to the doubling of the formulæ of the organic radicles. Wurtz also pointed out that the idea that the hydrogen molecule is compound must be extended to other elements, and that generally the simple bodies, like compounds, are composed of groups of atoms, and react not by combining but by exchange of elements.

The number of elements of which the molecular weight has been ascertained is, however, very small, and although the idea thus put forward by Wurtz undoubtedly applies to all the gaseous elements, and to bromine, iodine, sulphur, phosphorus, and arsenic, we now know that the only *metals* of which the density in the gaseous state has been satisfactorily determined, viz. mercury and cadmium, form distinct exceptions to the rule; we can therefore draw no conclusions of any value as regards the molecular composition of the metallic elements. It is a striking illustration of the slowness with which knowledge extends into that lower stratum which is governed by the text-books, that the view put forward by Wurtz, and which, with the above-mentioned limitation, is so clearly justified by facts, is almost universally disregarded by hand-books of chemistry; in fact, there is a most astounding superstition among students of chemistry that the elements generally have diatomic molecules.

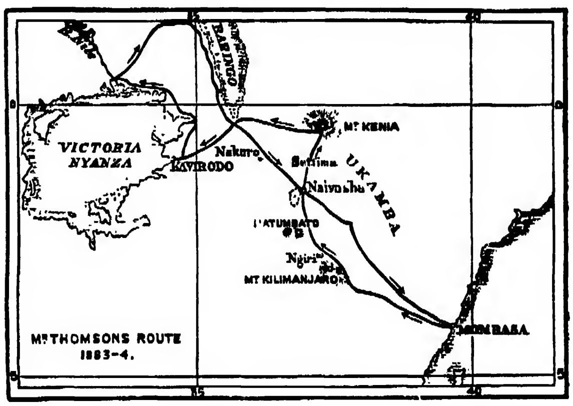
In 1855 Wurtz was led by the brilliant experimental results of Berthelot to discuss the formula of glycerin, and he was the first to point out that this body is to be referred to the type of three molecules of water; that, in fact, it can be regarded as an alcohol formed by the displacement of three atoms of hydrogen in three molecules of water by the radicle C_3H_5. Nearly all the alcohols known at that time could be referred to the type of a single molecule of water. Recognising the want of an intermediate series of alcohols, Wurtz was led in 1856 to the discovery of the glycols, and in this case again his work was of the highest value as a contribution to chemical theory.

Space does not permit of reference to the numerous other investigations of Wurtz, many of which have exercised an important influence upon chemical thought at the time of their publication. Only one must be mentioned, as it may ultimately prove to have been the first step towards the elucidation of the nature of the process of digestion in plants and animals. The investigation referred to is that on the sap of *Carica papaya*. He showed that alcohol precipitates from this a body presenting the characters of a strong digestive "ferment," capable of dissolving moist fibrin in large quantities. Experiments made with papaine, as the so-called ferment is termed, appear to show that papaine begins by combining with the "ferment," and that the insoluble product then undergoes gradual change in contact with water, the "ferment" being liberated and thus becoming free to do new work. There is much to indicate that mineral acids act in this way, and it is to be hoped that the suggestion put forward by Wurtz will not long escape notice, and that his investigation may be extended.

AFRICAN EXPLORATION

LETTERS addressed to the Secretary of the Committee of the British Association for the exploration of Kilimanjaro have just been received from Mr. H. H. Johnston, dated from the British Residency, Zanzibar, May 13. After consultation with Sir John Kirk, Mr. Johnston had selected the Mombasa route for Kilimanjaro, and was expecting to depart for that port in about a fortnight's time. The country between Mombasa and Chaga was said to be quiet, and to present no serious difficulties in the way. Mr. Johnston had succeeded in obtaining the services of three of the same bird-skinners that had been employed by Dr. Fischer, and of a botanical collector trained under Sir John Kirk, of whose kindness and assistance he speaks in the highest terms. Mr. Johnston, in spite of the trying climate of Zanzibar, was in excellent health, and had strong hopes of the success of the expedition.

We are pleased to learn that Mr. Joseph Thomson has arrived safely at Zanzibar from the expedition he undertook to the Masai region. It will be remembered that Mr. Thomson left England in the end of the year 1882, his object being to proceed by Mount Kilimanjaro to the almost unknown country of the Masai, and to settle the question of the existence of a Lake Baringo to the east of Victoria Nyanza. Mr. Thomson left Zanzibar in the



spring of last year, but after proceeding some distance found the country so disturbed owing to the recent passage of a German explorer, Dr. Fischer, that he was compelled to return precipitately to Mombasa. In July last, however, he started again, and has evidently accomplished his work in a way quite worthy of his previous record. Passing round the north-eastern side of Mount Kilimanjaro, Thomson proceeded north to Lake Naivasha, half-way between Kilimanjaro and Mount Kenia; then on to the latter mountain, and by way of Lake Baringo to the shores of Victoria Nyanza. This latter lake he skirted as far as the outlet of the Nile, returning by a more northerly route, striking the west coast of Lake Baringo, and proceeding south and south-east by Ukambani to Mombasa. It is satisfactory to record that no lives have been lost except by illness. The telegram which the Geographical Society have received from Sir John Kirk does not, of course, enter into minute details, but from its general tone it is evident that Mr. Thomson will have an interesting and instructive story to tell when he returns. The telegram does not state positively that Mr. Thomson found a lake where Baringo is placed on our maps, but as Baringo is mentioned as having been touched at, it seems most probable that the information obtained from natives by the sagacious Wakefield is correct. All the country traversed by Mr. Thomson's expedition to the north of

Lake Naivasha is new ground, hitherto untraversed by any explorer. Dr. Fischer in his recent expedition reached only as far as the lake just mentioned.

A NEW ASTRONOMICAL JOURNAL[1]

AN astronomical serial, under the auspices of the Observatory of Paris, will be a welcome addition to the literature of the science, and may well be expected to occupy a prominent place on the list of such periodicals.

Admiral Mouchez, in his introductory note, alludes to the great impetus which has been lately given in France to the progress of astronomy by the establishment or resuscitation of observatories, aided as well by national funds as by contributions from the municipal authorities of the places where they are located. In a few years these various observatories will be completely organised, the *personnel* consisting in part of astronomical students who have obtained their acquaintance with the practical branches of the science in the Observatory of Paris. The director therefore aims at providing a medium in the *Bulletin Astronomique* whereby the work of French astronomers may be speedily made known, and where at the same time an analysis of the contents of the principal foreign periodicals, &c., may be available to them.

The *Bulletin* will thus present two distinct sections: the first will be composed of observations of current interest, ephemerides of planets and comets, and memoirs or notices on various questions in theoretical and practical astronomy. The second will comprise as complete a *résumé* as possible of astronomical intelligence and an analysis of the principal periodicals and newly-published works. Further, in a supplementary section it is intended to introduce articles on subjects relating to the sciences allied to astronomy, as terrestrial physics, geodesy, and meteorology, not excluding points of interest in the history of the science: contributions from foreign astronomers are invited.

In the first four numbers of the *Bulletin* are articles bearing upon sidereal, planetary, and cometary astronomy. There is a series of measures of double-stars in 1883, made by M. Perrotin at Nice in continuation of previous series which have appeared in the *Astronomische Nachrichten*. M. Perrotin has habitually used powers of 750 and 1000: objects not too frequently measured of late will be found in his list, which is to be continued. MM. Henry have a note upon the planet Saturn as viewed in the refractor of 0·38 m. at the Observatory of Paris, in which reference is made to a narrow bright ring limited by a dark line, outside the principal division, the breadth equal to that of the division of Cassini, which they consider to be a new feature. It is stated that the Encke division has completely disappeared; notwithstanding extremely favourable atmospheric circumstances, nothing was remarked upon the outer ring except the narrow bright zone just mentioned. MM. Henry invite communications on this subject from other observers provided with large telescopes. M. Baillaud publishes observations of *Mimas* made at Toulouse between October 24, 1876, and December 5, 1883. The telescope employed has an aperture of 0·83 m., the mirror being the work of MM. Henry, the mounting by Secretan. A power of 335 was usually employed; the observations for the most part consist of the times of elongations, but during the opposition of 1882-83 M. Fabre succeeded in observing several conjunctions with the minor-axis of the ring N and S. From these observations M. Tisserand has drawn several conclusions respecting the motion of the satellite, to which he directed attention in a paper submitted to the Paris Academy of Sciences on January 28, and printed in the *Comptes Rendus*. He fixes the mean daily motion at 381°·9934, and his observations are compared with calculation on this hypothesis, the orbit being supposed circular. But he infers that there is an inequality in the mean longitude, of which the period is about five years, and the coefficient approximately 8°; further he finds that the eccentricity does not exceed one-tenth. The longitudes of the perisaturnium, deduced from observations during five periods, may be fairly represented on the assumption of an annual motion of 447°. It is intended to observe *Mimas* at Toulouse as frequently as possible, and, so far as circumstances admit, the same observer will undertake them, it having been found that observations made by different persons with the same instrument are not strictly comparable.

In the February number of the *Bulletin* M. Schulhof has the earliest notification of his discovery of the periodicity of the third comet of 1858, upon which he enters into details in the number for April; the most probable period of revolution resulting from the few observations which were secured in America (the comet was not seen in Europe) is 6·61 years, and the limits somewhat insecurely assigned are 5·80 and 7·54 years. As in other cases, this comet approaches very near to the orbit of Jupiter, to which we may attribute the limited dimensions of the orbit, according to M. Schulhof. There are several communications on Pons' comet, physical and otherwise; amongst them a note by MM. Trépied and Rambaud, of the Observatory at Algiers, on the remarkable variation in the head of the comet, observed on January 19, and one by M. Rayet on the *aigrettes*, &c., remarked near the time of perihelion passage. M. Radau treats on the theory of the heliostats, and M. Bigourdan on a means of rendering more convenient the use of the equatorial. We find also in these numbers of the *Bulletin* a description and plan of the buildings of the Observatory at Marseilles, by M. Stephan; and a list of discoveries of small planets and comets made at that establishment: amongst the latter we note that the discovery of the first comet of 1867 on January 25 is attributed to M. Coggia; at the time it was announced to have been made by M. Stephan, at least in a letter from M. Tempel, then residing at Marseilles, to the *Astronomische Nachrichten*; as Mr. Searle has shown that the comet is one of comparatively short period (thirty-three years) and may therefore want a name, it might be well to settle the point as to who was the actual discoverer. There is a note on an Observatory to be erected at La Plata, the recently founded capital of the province of Buenos Ayres; a director has been already nominated in the person of M. Beuf, an officer of the French Marine, formerly in charge of the Observatory of Toulon; 100,000 francs have been allowed for the Observatory and instruments, with an annual subsidy of 24,000 francs. Such liberal encouragement of science does honour to M. Dardo Rocha, the Governor of the Province of Buenos Ayres, and it is due to him to add that he had previously done much for recent progress in the Argentine Republic.

As a specimen of the miscellaneous articles in the *Bulletin*, we may mention M. R. Radau's interesting account of the recent crepuscular phenomena, in which he has availed himself of the numerous facts relating thereto which have been published in NATURE. He does not profess to decide upon the cause of these phenomena, or to make choice between the explanations which have been offered, but we may quote his concluding paragraph: "Ce qui semble prouvé, c'est qu'il s'agit ici, très-probablement, de phénomènes de réflexion, dus à la présence de matières finement divisées dont la nature reste à déterminer; la lumière ainsi réfléchie n'est, sans doute, que la lumière ordinaire du soleil couchant, colorée par transmission à travers les couches basses, chargées de vapeurs."

The typographical execution of the *Bulletin* leaves nothing to be desired. The March number contains a photolithograph of the aspect of Saturn as viewed at the Observatory of Paris on the 4th of that month.

[1] *Bulletin Astronomique*, publié sous les auspices de l'Observatoire de Paris, par M. F. Tisserand, &c. (Paris: Gauthier-Villars, 1884.)

MEASURING EARTHQUAKES[1]

II.—RESULTS.

IN this paper a short account will be given of the chief results of two and a half years' observations in the Seismological Observatory of the University of Tokio. The first instruments to be successfully used were the horizontal pendulum, or rather a pair of horizontal pendulums writing a multiplied record of two rectangular horizontal components of the earth's motion on a revolving plate of smoked glass, and also a very long common pendulum. The duplex pendulum, an astatic vertical-motion seismograph, and other instruments which have been mentioned in the former article, were added later.[1]

The earliest records were those of five small earthquakes in November 1880.[2] In the first of these the vibration of the ground lasted continuously for $1\frac{1}{2}$ minutes, and no fewer than 150 complete oscillations could be counted in the record. The shaking began feebly, speedily rose to a maximum, fluctuated irregularly, and died out very gradually. The greatest movement from side to side was less than one-third of a millimetre. Both

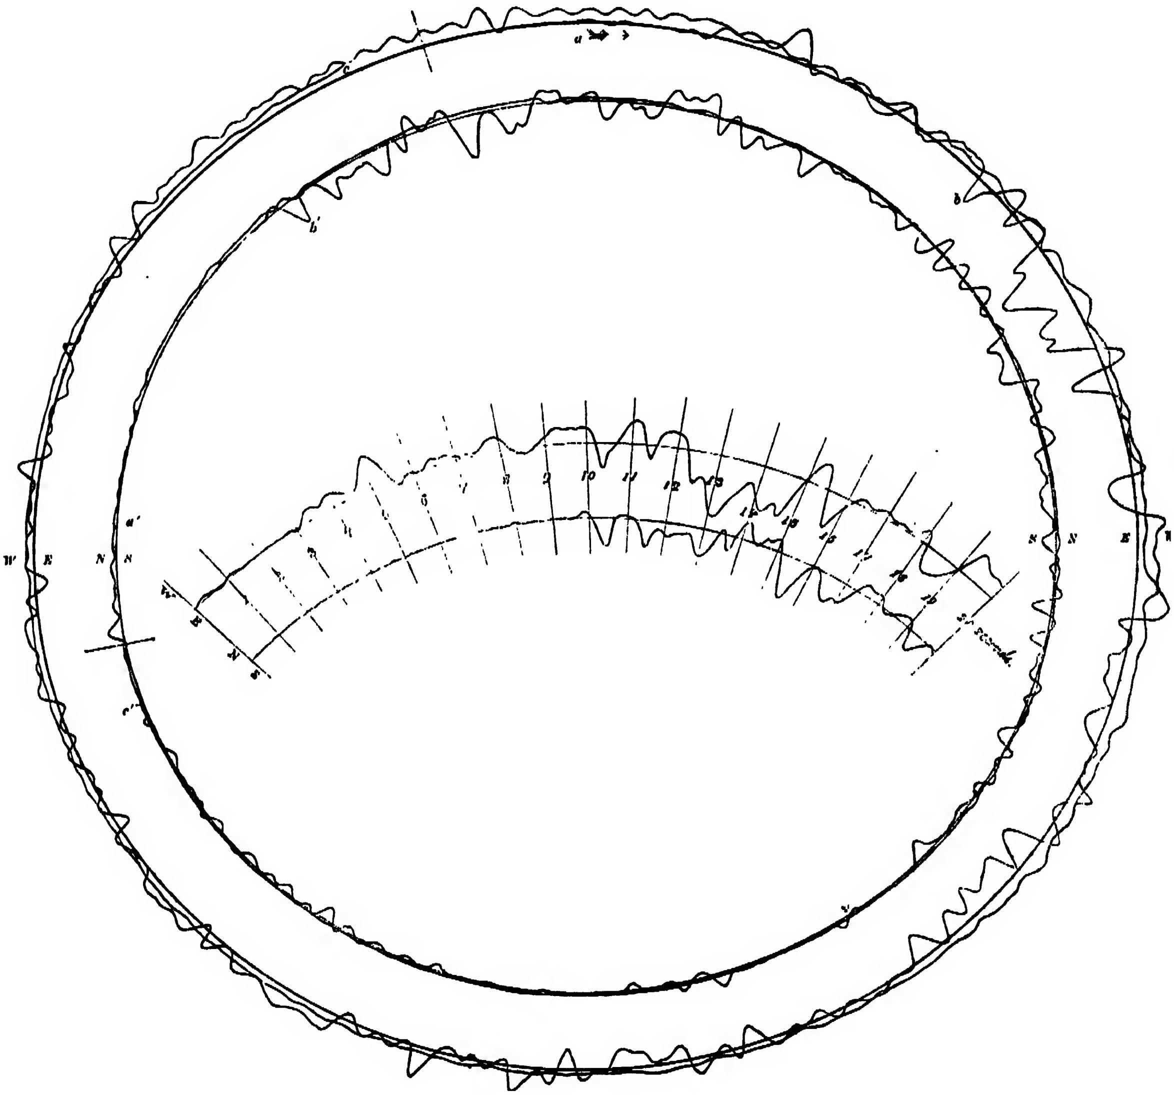


FIG. 7.

in amplitude and in period the successive waves were far from equal. A rough idea of the greatest velocity and greatest acceleration was, however, obtained by treating the greatest movement as a simple harmonic vibration, with a period of three-fifths of a second. This gave 1·6 mm. per second for the greatest velocity, and 16·4 mm. per second per second for the greatest acceleration, showing that bodies attached rigidly to the earth's surface must have experienced a horizontal force equal to about one-six-hundredth of their own weight. In three of the five earthquakes recorded in the same month the greatest range of motion was less than one-fifth of a millimetre. In all of them there were many and unequal vibrations, but in none was there any single impulse prominently greater than the other movements.

Later observations showed that these were fairly repre-

[1] Continued from p. 152.

[1] For a fuller account of the methods and results of these observations the writer may be permitted to refer again to his memoir on Earthquake Measurement, published as No. 9 of the *Memoirs of the Science Department of the University of Tokio.*

[2] Described in the *Transactions of the Asiatic Society of Japan*, vol. ix. p. 40.

sentative of a very large proportion of the earthquakes which occur so frequently in the Plain of Yedo. Earthquakes of this class do no damage to buildings, but they are strong enough to make their presence felt by the shaking and creaking of houses, and even, in the night, to startle residents out of sleep. Lamps and other pendulous bodies are frequently set into considerable oscillation through the long continuance of the disturbance, the period of some consecutive vibrations of the ground being nearly uniform and equal to the free period of the lamp. The shaking lasts rarely less than one and sometimes as much as ten minutes.

In some cases, however, the amplitude of the earth's motion is considerably greater; occasionally it rises to 5 and even 7 mm. With such an amplitude as this, and with the ordinary frequency which the earthquake waves have, the shock is more or less destructive—walls are cracked and chimneys are overthrown. The writer's observations do not include any earthquake of first-rate violence, but they show by several examples that in the alluvial soil of Tokio a sufficiently alarming and even damaging earthquake may occur, in which the range of horizontal motion is less than a single centimetre.

In the Yedo earthquakes the vertical motion is generally much less than the horizontal, and, as a rule, forms an unimportant part of the disturbance.

Fig. 7 is a copy, reduced to about half size, of the record of one of these more considerable earthquakes (on March 8, 1881), traced by a pair of horizontal pendulums on a revolving plate. The inner circle shows the N.S. component, and the outer circle the E.W. component of the displacement. The records begin simultaneously at the points marked *a'* and *a* respectively, and extend in the direction of the arrow over nearly two complete revolutions of the plate. At the point marked *c* in the outer circle, when the earthquake oscillations were slowly dying away, the writer (who happened to be present) withdrew the plate, to prevent the later portions of the record from confusing the earlier portions. By this time the earthquake had lasted for two minutes and a half, and some 200 vibrations had been registered. The motion, as recorded, was exaggerated in the ratio of 6 to 1; hence in the diagram as it appears here the displacements are nearly three times the natural size.

For the sake of exhibiting some interesting features of this earthquake more clearly, the records of the two components during the first twenty seconds of visible motion have been reproduced in the centre space of the diagram in such a manner that simultaneous parts of both are on the same radius. The short radial lines mark seconds of time. It will be seen that for three seconds the motions were very minute; then the E.W. seismograph became pretty sharply disturbed, but the other component was scarcely visible until the tenth second from the beginning.

During the tenth and eleventh seconds the phases of the two components agree in the main, but they soon diverge; and in the fifteenth second, when the motion is greater than at any other part of the whole disturbance, they differ by about a quarter of a period. Hence at that time points on the earth's surface were vibrating not in a rectilineal path but in *loops*. This is strikingly shown by Fig. 8, which shows the path (exaggerated in the ratio of 6 to 1) of a point on the earth's surface, during three seconds at this epoch in the disturbance. Starting from *p* at 13·7 seconds from the beginning of the earthquake, a surface particle described the tortuous path shown in the figure, and reached *q* three seconds later. Similar rapid changes of phase-relation occur throughout the rest of the disturbance, and in the slowly dying oscillations with which the earthquake drew to a close the writer noticed one of the pointers moving vigorously when the other was nearly at rest, and *vice versâ*.

The evidence, first clearly given in this earthquake, of the non-rectilineal character of the ground's motion, was confirmed by very many later observations. In fact in every case where the records were sufficiently large and well-defined to admit of a satisfactory comparison of the phases of the two components, the same thing was exhibited. And not only in those cases, but even in very minute earthquakes, instruments having two degrees of horizontal freedom, such as the duplex pendulum, showed in the most direct manner that the earth's movements consisted of a multitude of twists and wriggles of the most fantastic character.

An excellent example of a still sharper earthquake is given in Fig. 9—a record (reduced to half size) given by two horizontal pendulums with a multiplying ratio of four to one on a plate which was turning once in fifty-four seconds. The beginning of motion can be detected on the outer circle at *a*. At *b* and the corresponding point *b'* it increases somewhat suddenly, and during the next few seconds we have the principal motions, followed during many minutes by a long trail of lesser irregular oscillations, in which a marked lengthening of period may be detected towards the close. To allow the phase-relation during the principal part of the shock to be examined, lines (numbered 1 to 16) have been drawn by the aid of templates through corresponding points in the two records. An examination will show that the phase-relation changes: in fact when the two components are combined the movements are found to be loops, agreeing very closely with the larger loops of Fig. 10, which is a "static" record of the same earthquake given by the duplex pendulum. In a

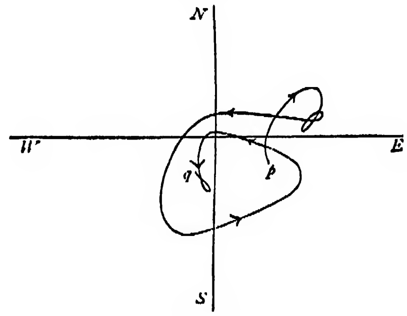

Fig. 8.

part of Fig. 10 the motions are so numerous and so much distributed over all azimuths, that the film of lamp-black has been completely rubbed away from a portion of the plate which received this record.

It frequently happens in the record of an earthquake that the motions which are first recorded are rapid vibrations, of short period and small amplitude, which are immediately followed by larger and less frequent movements. Sometimes, indeed, the former appear as a ripple of small waves superposed on larger ones. But in all cases where the short-period waves can be detected they die out early, and the later part of the earthquake consists of relatively long-period waves alone. Records of this class are exceedingly suggestive of the arrival of first a series of normal waves (that is, waves of compression and extension), constituting the rapid tremor, and then a series of transverse waves (that is, waves of distortion), forming the principal motions of the earthquake.

In fact it is difficult to explain the rapid changes of phase in the two components, or, in other words, the curved character of the horizontal movement, which most if not all the recorded earthquakes exhibit, otherwise than by supposing that the principal movements are transverse waves occurring in a plane not very much inclined to the horizon, and this conclusion is supported by the smallness of the vertical component.

It is true that the appearances presented by the diagrams could be accounted for by assuming the presence,

together, of normal and transverse waves, with a nearly horizontal direction of propagation; but in that case we should expect to find normal waves occurring alone at the beginning of the earthquake with much greater amplitude than they actually have. Other still less probable solutions might be referred to; but it is safe to say that the evidence furnished by these observations goes far to prove that the earthquakes of the Plain of Yedo consist chiefly of distortions, not compressions, of the ground, and emerge at Tokio in a direction not very far from vertical.

In the older seismology it was generally assumed not only that an earthquake consists mainly of one impulse, but that the motion of the ground has a definite direction, and that that is the same as the direction of propagation of the wave. All three assumptions were false. An old piece of seismic apparatus, based on these ideas, was a group of columns of various heights standing on a plane horizontal base. These were intended to show the direction and "intensity of the shock" by falling over. It is clear enough, however, that no appliance of this kind can give intelligible results from earthquakes of such complexity as those described above. The very word

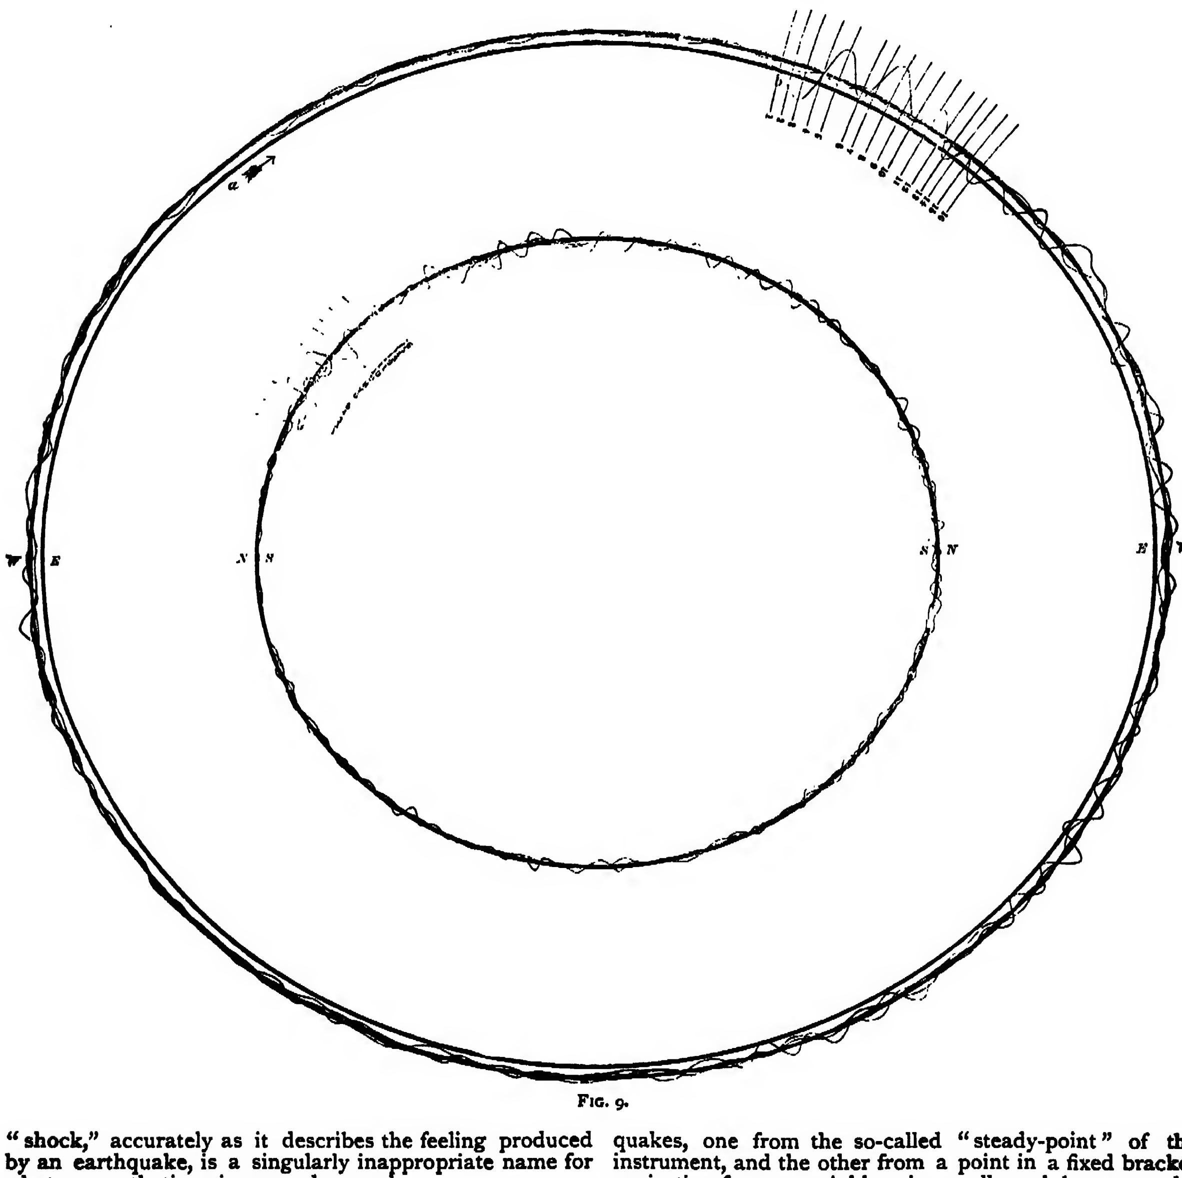

Fig. 9.

"shock," accurately as it describes the feeling produced by an earthquake, is a singularly inappropriate name for what an apathetic seismograph records.

As evidence of the accuracy of the apparatus by which the foregoing results were obtained, it should be mentioned that the records given at the same place by different instruments during the same earthquake were found to agree remarkably well. Further, the instruments were tested experimentally by placing them on a shaky table, and obtaining, side by side, two records of table-quakes, one from the so-called "steady-point" of the instrument, and the other from a point in a fixed bracket projecting from a neighbouring wall, and known to be truly steady. When the table was shaken in such a way as to give records resembling those of actual earthquakes, the agreement of the two showed conclusively that the steady-point of the instrument did remain very nearly undisturbed, and that the records were in all important particulars substantially correct.

We have then the means of accurately observing the

nature of the surface motion at an earthquake observatory. But this of itself tells us nothing of the speed and direction of transit of the disturbance, particulars which are only to be learnt by connected observations made at several stations. Any one earthquake, as a whole, lasts far too long and begins too gradually to admit of the measurement of time-intervals between its arrival at different points, but if we can identify any single vibration in the records given at several stations—spread over a moderate area, and connected telegraphically with each other—the problem admits of a fairly easy solution. A recording seismograph at each station will give a complete record of the earthquake as it appears there, and if, during its progress, time signals be sent from one station and marked on all the revolving plates, it will be possible to

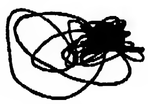

FIG. 10.

determine the differences in time of arrival of *the same phase of the same wave* at the successive stations in the group. From this, if the stations be sufficiently numerous, the speed and direction of transit, and even the origin of the disturbance, may be found with more or less precision. But all this depends on our being able to recognise at the various stations some one wave out of the complex records deposited at each, and, especially in view of the curvilinear nature of the motion, it would be hazardous to say without trial whether this can be done. To ascertain whether it can be done, and if so to organise groups of connected stations to carry out the scheme roughly sketched above, should be the next step in observational seismology. J. A. EWING

University College, Dundee

NOTES ON A FEW OF THE GLACIERS IN THE MAIN STRAIT OF MAGELLAN MADE DURING THE SUMMERS OF 1882-83 IN H.M.S. "SYLVIA"

THE western part of the main Strait of Magellan, to which my remarks are confined, lies between rugged and abrupt mountains, of rock mainly crystalline, but in parts of slate.

The highest peaks are not over 4500 feet high, and the height of the snow-line is about 2700 feet. The land is cut up into small areas by numerous and tortuous channels, and, on the southern side certainly, no large masses of land exist. The mountain ridges are mostly sharp and steep, and afford but little area for snow to lie in quantities, but wherever a mountain slope is moderate, there it accumulates, and forms *névé*, which may or may not descend to lower levels.

From this it will be seen that the glaciers spoken of are small, only one snow-field, the "Northbrook," being of any size. Much larger glaciers of course exist in these regions, but were not in my beat, lying either to the south about Mount Darwin and Mount Sarmiento, 7000 feet high, or to the north on the mainland bordering the western channels.

Some ice-masses are ridiculously small, one I remarked, at the end of summer, on a ledge a little below a very sharp ridge 2700 feet high, was not probably larger than 10,000 tons. It lay entirely bare of snow on the southern or shady side of the ridge, and was of blue ice.

It is evident that it is the enormous amount of the supply of material which accounts for the existence of glaciers from such small origins, and in fact the deposition of snow is going on all the year round for the majority of hours out of the twenty-four. The winds are eternally from the western quarter, are usually fresh, and, arriving moist from the Pacific against the rampart of mountains, rush up their western slopes into the colder regions, where constant condensation takes place. During my stay—about eight months—the summits of the higher snow-fields (3500 to 4500 feet) were only seen twice or thrice, so continually are the mists around them.

The daily duration of rain at the water-level during the *Sylvia's* stay of about eight months west of Cape Froward was eleven hours out of every twenty-four. The quantity corresponded to a yearly fall of 180 inches.

Though the mean temperature for the year is low, the range, summer and winter, is very small, so that flowering plants which grow on the borders of the glaciers and on exposed hills perish in England, from inability to withstand the sudden changes and lowness of the winter temperature.

The inference would seem to be that a Glacial period need not so much depend upon extreme cold as on an unlimited condensation with an equable temperature, low enough at moderate altitudes to form snow.

The glaciers are nearly entirely devoid of erratic blocks or surface moraines. Coming, as they do, over everything, down a hill-side, there is seldom an overhanging mountain to discharge blocks; where there is, the rock is so solid that the very slight changes of temperature (for the sun has no power here) is not sufficient to disintegrate it. Even the glaciers therefore that descend nearly to the sea are quite clean and spotless to the very end.

I could never make out any raised beaches, nor other signs of former lower level of the land; all the evidence is the other way. No beaches exist at the water-level of the present day. There is not enough sea in these confined channels to wash away the land, even if it was of a softer nature. The steep rocky mountain-sides dip clean into the water nearly everywhere. Thick moss covers the hill-sides wherever it can get a hold, so that it is not easy to see the true contours of them, and a more experienced eye than mine might perhaps detect a raised beach where I have failed to do so.

Glacier from Mount Wharton

Mount Wharton, 4400 feet high, on the south shores of Long Reach, sends down what I consider a rather remarkable glacier, despite its small size.

The upper part of the mountain, of a tolerably gentle slope, is of an area of about four square miles. This terminates everywhere in steep precipices, over which in different directions the blue ice, which can be seen lining the edge, tumbles, and forms *glaciers remaniés* in hollows at lower levels in several places. On the south-eastern side only is a steep slope, down which, after a series of ice-falls, a leg of glacier, one-third of a mile wide, and one mile and a half long, extends to within 150 feet of the sea-level, and a quarter of a mile from the shore. At its end it abuts against a hill, and from the fact of the ground sloping away on either side from this glacier leg, it appears that this slope is a ridge, down which the glacier comes, as it were, astride. Where it strikes the hill, it divides, and sends a final short leg towards the sea on either side of the peninsula formed by the hill.

The slope of the lower part of the glacier is 15°, and it is much crevassed, and squeezed into pinnacles and ridges, so that, when tolerably clear of snow, it looks like frozen waves.

There is no moraine on it, and, wherever I could see, it lies on the solid rock, but a few stones are carried along at the bottom of the ice, and, at its end, where it abuts against the hill, the latter is a mass of loose rounded stones (very few angular ones), up to the limit occasionally reached by the glacier, which is well and curiously marked by a narrow belt of trees, growing on the edge of the tumbled stone moraine. Behind them the hill is of solid rock, bare or moss-covered (see illustration).

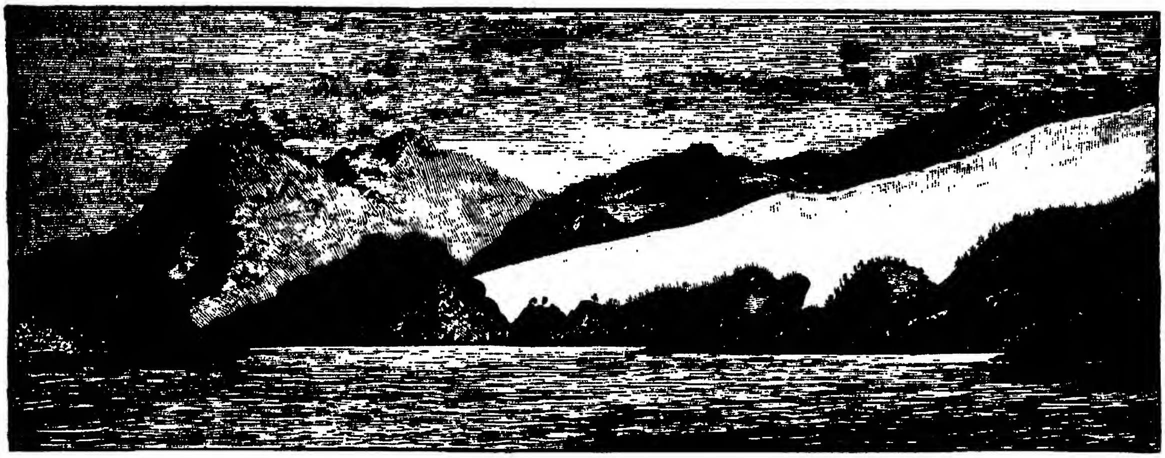
The side limit of the glacier, where it sometimes flows down the slope on its right and left, is also marked by a similar line of trees, the intervening space of about 300 yards being partly strewn with loose stones and coarse gravel, and partly perfectly bare, highly polished, striated rock. This rock has a somewhat remarkable appearance, as it is composed of a fine dark stone (a metamorphosed slate?) with intrusive parallel veins of white crystalline rock. The bands of black and white are very even in width, and there is as much of one rock as the other, so that, as the strike of the veins is in the same direction as the flow of the glacier, they look, at a little distance, like gigantic striæ.

I marked the foot of this glacier in December 1882, and found by March 1883, after the summer, that it had retreated 30 yards. After the winter, I fully expected to find that it had again advanced, but in December 1883 the edge of the ice was 50 yards farther back than in the previous December. They reported a very mild winter at Sandy Point, but I was not prepared to find the glacier retreating throughout the year, as it was manifestly at its full limits not many years ago.

I could not procure any evidence as to its rate of motion. The sides are so broken up, by great pieces falling off and slipping down the slope, that it is almost impossible to get at the main body of the ice to put a mark in.

The head of West Havergal Bay, into which the glacier stream falls, is filled with a level bottom of sand with about 10 fathoms of water over it. This has a very steep edge to the deeper part of the basin. I imagine this to have been the delta formed by the glacier stream, when the land was at a slightly higher level. It is very rare in the Straits of Magellan to have anything but uneven, rocky bottoms to these deep basins, and they are generally steep to the edge of the shore. I have only found these sandy flat bottoms in the vicinity of glaciers, and as a sandy flat always forms around the *embouchure* of the glacier streams, a subsidence of the land would account for the existence of flats under water.

The hill-sides around Havergal Bay, where bare, show glaciation to a height of about 700 feet above the present sea-level. I think the land must have been higher when the ice was at this height, as the channel just below some of these marked hills being 60 fathoms deep, it would require the glacier to be 1000 feet thick, which seems to me hardly possible with such a small area for the production of *névé* as there is now, even supposing a greatly



Havergal Bay, Strait of Magellan. End of Glacier from Mount Wharton.

increased fall of snow and a much lower average of temperature than at present.

I visited one of the *glaciers remaniés* on the north-west side of Mount Wharton. It lies in a hollow about 1500 feet above the sea, and at the foot of cliffs 1000 feet high or more, and is three-quarters of a mile long by 400 yards wide. It is an excellent example of regelation, as the fragments which form it must be dashed to small pieces in their fall. It was at the end of summer, and only insignificant bits were coming over the cliff from the ice-field above. These fell on the *glacier remanié* broken into minute fragments with a patter as of heavy hail. Larger masses would be similarly broken, and yet the ice-mass was as clear and compact as if it had never been disturbed.

There were signs here on all sides, in the striations and *moutonnée* shape of all the rock above it, that this reorganised mass was once much larger; and 500 feet below, on a tolerably level part of the otherwise steep hill-side, bordering the stream that issues from the glacier, were low lines of moraine that were evidently once at the lower part of its sides.

A snow-field on a flattish mountain 3100 feet high, near Mount Wharton, has no proper glacier, but the ice falls over precipices and forms *glaciers remaniés*.

Glacier from Mount Wyndham

Mount Wyndham, on the opposite side of the Strait to Mount Wharton, sends a glacier down a valley, but has no surface moraine nor blocks. Its length is about two miles and a half, and the width, at the bottom, half a mile. Like others, it is very steep, and its surface is broken into pinnacles with deep crevasses. As I never saw the landward side of Mount Wyndham, I cannot exactly say what other glaciers may take their rise in it, nor what the size of the snow-field may be, but it probably does not exceed more than four or five square miles.

The foot of the glacier is not more than 100 feet above the sea, and is half a mile from the head of Glacier Bay, in a broad flat between the mountain slopes. A thick belt of tangled forest intervenes. This glacier is much shrunk also, a wide space of ground, covered with rounded stones, sand, and gravel, extending all round the foot to the edge of the trees in front, and the hills at the sides.

Signs of glaciation are abundant about this glacier, at far higher levels than it now reaches. Glacier Bay itself has been filled with it. This is a deep basin (70 fathoms deep) with islands stretching across its entrance. Rock Island, the largest of these, is *moutonnée* to the top, 560 feet, and the striæ are plain to see on its smooth

precipitous sides. Several perched blocks stand on the mountain-sides about, but as I did not visit these, I cannot say whether they may not have simply come from the heights above, though their precarious positions would indicate not.

Outside Rock Island is another area of even, sandy, and muddy bottom, in from 10 to 6 fathoms water, with a steep edge to the deep water of the Strait, similar to that at the head of Havergal Bay. This, I take it, must have been formed by the glacier stream, and was once its delta when the land was higher.

A sandy flat, mixed with rounded stones, now surrounds the glacier stream where it falls into Glacier Bay, and only wants a subsidence of the land to convert it into a counterpart of Havergal Bay. I do not know how else to account for this flat outside Glacier Bay, which was as unexpected as it was welcome, since it forms one of the best anchorages in the Straits, where even bottoms for the anchors are at a premium.

Northbrook Glacier

A snow-field in King William's Land between Northbrook Sound and Beaufort Bay is the largest in these parts, but I do not know much of it. It lay unfortunately just outside my work, and was so uniformly covered with clouds that I only saw the summit once.

It has probably an area of from fifty to seventy square miles. It is a flattish mountain about 4500 feet high. The ice descends on all sides in a succession of ice-falls, exhibiting lines of blue ice, most beautiful to see, about two or three miles long. Only when within 800 or 1000 feet of the sea is a true glacier formed.

These glaciers at the head of Northbrook Sound reach to within 100 feet or so of the shore level. In Beaufort Bay I rather think they reach the water. In Northbrook Sound the glacier at a mile from the coast, is about a mile and a half wide, but it is shortly after broken by a protruding hill, and divides into two legs, each half a mile wide. This glacier was also much shrunken. It brings down no moraine, and flows over solid rock.

W. J. L. WHARTON

NOTES

THE Council of the Mathematical Society have awarded the first De Morgan Gold Medal to Prof. Cayley, F.R.S.

M. PASTEUR has been awarded a gold medal by the Société Centrale pour l'Amélioration des Races des Chiens for his work on rabies.

THE jury of the International Horticultural Exhibition at St. Petersburg have awarded a gold medal to Dr. Regel, Director of the St. Petersburg Botanical Garden. The other awards for scientific work were to Dr. Gobi, the Russian algologist, for his remarkable herbarium; to Mr. Hartnack, for his microscope; and to Countess Zichi for her picture representing the *Serapias*. A gold medal was awarded to the Japanese University of Tokio for its collection of fruits.

M. JAMIN has been elected Perpetual Secretary in the Section of Physical Sciences of the Paris Academy in succession to the late M. Dumas.

DR. ADAM PAULSEN has been appointed Director of the Danish Meteorological Institute in succession to the late Dr. Hoffmeyer. Dr. Paulsen was the Chief of the Danish Polar Expedition to Godthaab.

PROF. W. GRYLLS ADAMS, as President of the Society of Telegraph Engineers and Electricians, will hold a *conversazione* in the Museum, Physical Laboratory, and Art Galleries of King's College on Thursday evening, July 3, from nine to twelve o'clock.

BY invitation of the Executive Council of the International Health Exhibition, a conference of the Society of Telegraph Engineers and Electricians will be held in the Conference Room of the Exhibition, South Kensington, on Friday, July 4. The chair will be taken by Prof. W. Grylls Adams, F.R.S., President of the Society, at 11 o'clock a.m., when the following paper will be read and discussed: "On Electric Lighting in Relation to Health," by R. E. Crompton, member. An adjournment for luncheon will take place at 1.30, and at 2.30 the following paper will be read and discussed, viz.: "The Physiological Bearing of Electricity on Health," by W. H. Stone, M.A., M.B. Oxon, F.R.C.P., member.

A LARGE number of guests, including ladies, assembled by invitation of the President of the Royal Society at a *conversazione* held at Burlington House on Wednesday last week.

ARRANGEMENTS have been made by the Council of the Scottish Meteorological Society for the completion this season of the Observatory of Ben Nevis. The first portion of the Observatory was, it may be remembered, opened in October last, and since the observers went into residence continuous hourly observations have been made of the conditions of the atmosphere at the top of the Ben, with special reference to temperature, pressure, humidity, and motion. From the discussion of these, and what were daily made by Mr. Clement L. Wragge in the summers of 1881 and 1882, by the Secretary, Mr. Buchan, the Council have been fully confirmed in the high expectations they had formed concerning the value of a high-level station, both in its bearing upon general meteorological problems, and also with reference to possible forecasts for the British Islands. The problem, however, is great and many-sided, and is one which can only be solved after much patient investigation and labour. The additions to be made to the Observatory will just double its size, and enable the three observers—who during the winter have been considerably cramped in their one apartment —to work under more comfortable conditions. On the south of the present doorway there is to be erected a shelter for tourists. On the north side of the existing building there is to be erected a new sitting room or office, 15 feet by 13 feet, while off this apartment there will be two bed-rooms, each 9 feet by 7 feet. The office will be lighted by two windows; and in each bed-room there will be one window. Opening from the east side of the office is a short passage leading to an octagonal tower, the walls of which will be 6 feet in thickness, and its internal diameter 8 feet. The tower, which will be 25 feet high, will be divided into three apartments, the lower being a dark chamber for photographic purposes, the centre one a spare room, and the upper a depository for observing instruments. The stonework of the tower is carried up to the height of the ceiling of the second chamber. The upper room is a superimposed wooden cabinet, the exposed parts of which are covered with lead. The floor of this apartment is carried out over the stone walls and firmly fixed to the tower below by iron rods, and to the roof above by strong wooden braces, so that it cannot possibly be upset. In the upper chamber are four windows, one facing each of the cardinal points of the compass, and at one of these is a ladder leading down to the roof, so that, should the doorway be blocked by snow, this would form a means of exit for the observers; the ventilating and smoke pipes, which are contained in one casing, are carried up through the roof of the tower, while, rising 6 feet above the ventilator, will be two anemometers, specially constructed by Profs. Chrystal and Crum Brown, for continuously recording the direction and velocity of the wind. These instruments will be self-registering, the apparatus for this purpose being in the chamber below, where it will be accessible at all times. On the eastern face of the tower a door has been left, so as to provide for future extension for magnetic and seismic observations. The estimated cost of the

completion of the Observatory in the manner now explained will be 800*l*., which is, however, irrespective of a heavy item of charge for conveying on horseback the materials to the top of the hill. It is understood that the cost of equipment and maintenance of the Observatory heretofore has been heavier than was anticipated. The directors intend shortly to make a fresh appeal for funds to the public, which will no doubt be as liberally responded to as was their last.

THE first annual conference of the National Association of Science and Art Teachers will be held in the Liverpool Institute, Mount Street, Liverpool, at half-past two on Saturday, June 21. Prof. Silvanus P. Thompson, D.Sc., will preside. The following arrangements have been made for the day's proceedings:—Meeting in the vestibule of the Free Museum, William Brown Street, at 10.30 a.m. The members and delegates will view the museum, library, and art gallery. At 12.5, train to Bootle from L. and Y. station, for Alexandra Dock, to view the National Liner *America*. Return per train to Liverpool, for refreshments and inspection of Liverpool Institute and School of Art. Business meeting at 2.30 p.m. Paper by Prof. Thompson at 7 p.m.

PROF. STRICKER of Vienna has in the press a work on which he has been engaged for some time. Under the title "Physiologie des Rechts" he has applied modern scientific methods to the investigation of ethical problems. The aim of the book is to examine the correlative conceptions of right and law in the light which is cast on them by the conceptions of development and of society as something more than a mechanical aggregate of independent units. The first part of the inquiry is psychological. The second treats of the relations of ethics to jurisprudence, dealing with the question of connection of right with might as part of the general problem of evolution. The third discusses the question of punishment and responsibility. The book is to be published by Toeplitz and Deuticke of Vienna.

WE have on several occasions drawn attention to the good work which is being done by the Royal Victoria Coffee Hall, Waterloo Bridge Road. The entertainments provided are healthy, instructive, and popular; among other items in the programme are lectures by some of our best known men of science. The undertaking is in want of funds to further extend operations, and those willing to contribute to a really good cause should communicate with Miss Cons at the Hall.

THE death is announced of the eminent scientific geographer, Dr. G. von Boguslawski; his "Handbuch der Oceanographie" has only just been published.

TORTOISES and snakes are intimately associated together in Chinese mythology and records of natural history, and hence one of the commonest emblems current in China, and a very favourite ornament, is a tortoise encircled by a snake. During the Chow Dynasty (B.C. 1122-255) these animals were chosen as emblems of martial security against attack, from the defences which nature has given them in the shell of the one and the scales of the other, and to the present day flags bearing a device in which they both appear as emblematic of this idea are usually carried by troops in the field. But it is further commonly stated as a fact that the greatest affection exists between these two creatures. Is there any ground for this last assertion? A passage in a letter lately published in the *China Mail* from a correspondent in Shanse seems to give a certain colour of probability to it. He says that one evening as he was walking on the bank of a certain river he saw a tortoise swimming across the current. Having his rifle with him he fired at the creature, upon which the tortoise dived under water, and a snake, cut in two by his bullet, floated on the surface. From the writer's account the snake appears to have been crossing the river on the back of the tortoise.

WE trust that the effort being made by the Sunday Society to obtain the opening of the Health Exhibition on Sundays will be successful. In the memorial of the Society to H.R.H. the Prince of Wales and the Executive Council of the International Health Exhibition, a letter is given from Sir Joseph Hooker to Prof. Tyndall, in which the former insists strongly on the beneficial results to the working-classes of the opening of Kew Gardens on Sunday. In this letter Sir Joseph Hooker says:—"If there is one matter that gratifies me more than another in respect of the administration of the Kew Gardens and Museums by the Government, it is the opening them to the public on Sundays. On no day of the week have we more interested visitors or more of that class which we should wish to see profiting by the instructive contents of this Institution. The Museums especially are crowded, and when it is considered that the exhibits in them are not of articles that strike the eye or gratify the senses of colour or form, the interest they excite is almost to be wondered at. The artisan classes are great frequenters of these Museums with their wives and families, and it is pleasing to see the delight with which the children recognise such articles as the sugar-cane, the coffee-plant, and its products, and the various implements used in their preparation, manufacture, &c. I should add that this interest in the instructive character of the Gardens is largely on the increase, and is manifest to the most careless observer. It is further accompanied by a marked improvement in the conduct of certain classes which were formerly troublesome in many ways and a nuisance to quiet visitors. It speaks volumes for the moral effect of the Sunday opening when I add that such classes no longer exist at Kew. Whether it is that such no longer come, or that coming they now behave themselves, is immaterial: the moral gain is great. During the last two years we have had in each year a million and a quarter of visitors, of whom the greater proportion are Sunday afternoon arrivals from every quarter of the Metropolis and its surroundings. Let the numbers speak for themselves:—1882, Sunday visitors, 606,935; week-days, 637,232; 1883, Sundays, 616,307; week-days, 624,182." Equally beneficial results, we are convinced, would follow the opening of the Health Exhibition on Sundays.

THE World's Industrial and Cotton Centennial Exposition, sanctioned by an Act of Congress of February 1883, and to be opened at New Orleans, December 1, proposes to bring together a magnificent international collection of plants and shrubs, in the largest conservatory ever erected, 600 feet in length, 194 feet in centre, with glass tower 90 feet in height, where Mexico and Central America will be the principal exhibitors. Six lakes will be contained in the grounds, round which will be groves of cedar, pine, pomegranate, magnolia, lemon, palm, orange, cocoa-nut, banana, &c. But the United States Bureau of Education in a preliminary circular calls attention to the very large and varied collection which will be found there of educational appliances of every description; plans of schools and methods of teaching all classes of scholars from the deaf and dumb or imbecile to the technical or university student; books in all their parts and stages; stationery, and materials for drawing, extending to photography; maps; instruments and apparatus mathematical, medical, and musical. The Bureau gives the managers of the Exposition credit for considering the improvement of schools as among the most beneficial results to be gained by their efforts.

THE Presidency of the Social Science Association for the ensuing year has been accepted by Mr. G. J. Shaw-Lefevre, M.P., First Commissioner of Works. The preparations for the Annual Congress, which is to take place at Birmingham from September 17 to 24, are being vigorously pushed forward by the different Local Committees, and a largely attended and success-

ful meeting is anticipated. It is sixteen years since the Association met for the second time in Birmingham, and twenty-seven years since it held, in 1857, its first meeting, which also took place in that town.

We learn from a communication of Dr. Glasenap to the Russian newspapers that there are in Russia the following private observatories: at Pervin, near Torjok, in the Government of Tver, belonging to General Maievsky; at Bunakovka, in the Government of Kharkoff, belonging to Prince Liven; and at Odessa, belonging to M. Gildesheim. A Polish gentleman, M. Wuczihowski, is building a private observatory at Belkave, near Breslau; and a Russian gentleman, W. P. Engelhardt, has a fine observatory at Dresden. The last is provided with an equatorial which has a 12-inch refractor, and is one of the most perfect telescopes. The equatorial is provided also with a 4-inch telescope with a large spectroscope. There is also a 6-inch searcher for comets, with a wide field of sight, and a selection of the best physical instruments.

The Rev. John Stevenson is preparing for publication, by subscription, through Messrs. Blackwood and Co., a "Flora of British Fungi (Hymenomycetes)," with illustrations by Worthington G. Smith, F.L.S. The author states that he has the co-operation of the most eminent mycologists. It may be added that the value of the "Flora" will be greatly enhanced by embodying the views of Fries, contained in his "Monographia Hymenomycetum Sueciæ," a work which cannot now be obtained, only 100 copies having been originally printed. The issue of the work will depend on a sufficient number of subscribers being received by an early date, in which case the first volume will be published without delay.

A general meeting of the Mineralogical Society will be held in the library, Museum of Science and Art, Edinburgh, on Tuesday, June 24, at 12 o'clock noon. The following papers will be read:—Forms of silica, by John Ruskin, D.C.L., Slade Professor at Oxford (communicated by the Local Secretary for Scotland); application of the periodic law to mineralogy, by Thomas Carnelley, D.Sc., F.C.S., Professor of Chemistry, Univ. Coll. Dundee (communicated as above); the origin of the andalusite schists of Aberdeenshire, by John Horne, F.R.S.E., H.M. Geol. Survey; on the occurrence of prehnite and other zeolites in the rocks of Samson's Ribs and Salisbury Crags, by Andrew Taylor, F.C.S., A.G.S.E. (communicated as above); on a new locality for zoisite, by W. Hamilton Bell, F.G.S.E. (communicated as above); on diatomaceous deposits in Scotland, by Prof. W. I. Macadam, F.C.S., Hon. Sec. G.S.E.; notes on the albertite beds of Strathpeffer, Ross-shire, by William Morrison, M.A., Academy, Dingwall (communicated as above); kyanite localities in the north, and staurolite from Presholme, Enzie, Banffshire, by Thomas Wallace, High School, Inverness; the crystallography of bournonite, by H. A. Miers, B.A., British Museum, Nat. Hist. Dept.; notes on the metallic veins of the Upper Hartz, Germany, by H. M. Cadell, B.Sc., H.M. Geol. Survey (communicated as above); Scottish localities for actinolite, by Rev. W. W. Peyton; on a peculiar development of crystals of tourmaline from Lockport, N.Y. County, U.S., by R. H. Solly, F.G.S.

Father Denza, Director of the Meteorological Observatory of the Turin Exhibition, is taking steps for organising observations on board the Godard captive balloon, which ascends to an altitude of from 200 m. to 300 m. The principal scientific features of the Turin Exhibition are:—(1) The collection exhibited by Prof. Sylvestri, Director of the Etna Observatory, and containing a number of specimens of amber collected on this mountain. (2) The methods employed by M. de Rossi, head of the newly-created Seismographic Service for issuing warnings of earthquakes and describing the observed phenomena. M. de Rossi has issued a catalogue of 200 pages octavo describing the principal objects exhibited, the instruments tried, the methods adopted, and the results arrived at. (3) An historical Borgho, exhibiting mediæval costumes, buildings, instruments, furniture, and methods of working. A number of people of both sexes wearing the costumes attend to this part of the Exhibition.

Three Ministers inaugurated in state, on June 14, the National Exhibition of Rouen, which will be international for electrical purposes. In the official speeches allusion was made to the Universal Commemorative Exhibition which is to be held in Paris in 1889. The site selected is the celebrated Park of St. Cloud, and a Crystal Palace is to be built on the ruins of the old Imperial palace.

Under the auspices of the Norwegian Association for the Promotion of Fisheries an establishment for the hatching of cod and soles' ova has been prepared near Arendal in the Christiania Fjord. From the excellent results already obtained it has been decided to found another hatching station near Christiania.

A large copper basin consisting of small pieces riveted together and several wooden kegs containing "bog butter" were recently found at a depth of 7 feet in a peat-moss, Kylealsin, Skye. The kegs are each hollowed out of a solid block of wood, and show traces of burning all over the surface. The largest measures 1 foot 7 inches in height and 3 feet 6 inches in circumference.

The additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii* ♂) from South Africa, presented by Mr. J. Bulteel; a Bonnet Monkey (*Macacus sinicus* ♀), a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by the Committee of the Latimer Road Mission; two Black-eared Marmosets (*Hapale penicillata* ♂ ♂) from South-East Brazil, presented by Mr. J. H. Bentley; two Vulpine Phalangers (*Phalangista vulpina*) from Australia, presented respectively by Mr. McClellan and Mr. Jay; a Marsh Ichneumon (*Herpestes galera*) from South Africa, presented by Mrs. Frank; two Angolan Vultures (*Gypohierax angolensis*), a White-necked Stork (*Ciconia episcopus*), an African Tantalus (*Pseudotantalus ibis*) from West Africa, presented by Mr. Thomas J. Alldridge; a Spur-winged Goose (*Plectropterus gambensis*) from West Africa, presented by Mr. J. B. Elliott; two Mute Swans (*Cygnus olor*), European, presented by Mr. H. Welch Thornton; two Angulated Tortoises (*Chersina angulata*) from North Damara Land, presented by Mr. F. R. Hemming; a Slow-worm (*Anguis fragilis*), a Common Viper (*Vipera berus*), British, presented by Mr. T. E. Gunn; a Bonnet Monkey (*Macacus sinicus* ♂) from India, four Muscovy Ducks (*Cairina moschata*), five Royal Pythons (*Python regius*) from West Africa, deposited; an Echidna (*Echidna hystrix*), a Brush Turkey (*Tallegala lathami*) from New South Wales, two Red-cheeked Colys (*Colius erythromelon*) from South Africa, four Bronze-winged Pigeons (*Phaps chalcoptera* ♂ ♂ ♀ ♀) from Australia, a Great-billed Parrakeet (*Tanygnathus megalorhynchus*) from Ceram, a Mealy Amazon (*Chrysotis farinosa*) from South America, four White Storks (*Ciconia alba*), European, a Kingfisher (*Alcedo ispida*), British, purchased; a Collared Fruit Bat (*Cynonycteris collaris*), a Japanese Deer (*Cervus sika* ♀), six Chiloe Wigeons (*Mareca chiloensis*), four Chinese Blue Magpies (*Cyanopolius cyanus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

Recent Improvements in Astronomical Instruments.—Acting under the directions of the Secretary of the Navy, Prof. Newcomb last year visited the principal Observatories on the continent of Europe for the purpose of collecting information relating to the most recent improvements in astronomical

instruments and methods of observation; and in a Report which has been laid before Congress and printed he has embodied the main results of his journey. The establishments visited were the Observatories of Paris, Neuchâtel, Geneva, Vienna, Berlin, Potsdam, Leyden, and Strasburg, and the workshop of Messrs. Repsold at Hamburg. Prof. Newcomb acknowledges the cordial reception he met with from the directors and astronomers of the various observatories, and the facilities everywhere afforded him for the execution of his mission. Most interest attached to the great refractor constructed for the Observatory at Vienna by Howard Grubb of Dublin, which was completed in 1881, but, owing to various delays, had hardly been brought into active operation at the time of Prof. Newcomb's visit in April 1883. Nevertheless he was able to compare it in several respects with the great Washington telescope, which is of only one inch less aperture. He considers that "as a piece of mechanical engineering it reflects great credit upon its designer and constructor." The chief drawback he remarked, the reasons for which were not evident either to him or to Dr. Weiss, the Director of the Observatory, consisted in the failure of the friction-rollers for easing the motion in declination; this motion was found much more difficult than in the case of the Washington telescope. Prof. Newcomb also points to the absence of any rough setting either in right ascension or declination, and the impossibility of seeing the pointing in declination except when the observer was at the eyepiece. With regard to the objective he considers, from such observations as he was able to make, that, "if any defects exist, they are so minute as not to interfere in any important degree with the finest performance of the instrument," and its proper figuring is rightly considered the most difficult task in the construction of a large telescope. In the workshops of Messrs. Repsold at Hamburg Prof. Newcomb had the advantage of meeting M. Otto Struve, and discussing with him the arrangements for mounting the 30-inch refractor intended for the Imperial Observatory at Pulkowa, the most striking feature in which is the absence of friction-rollers from the declination axis; he describes the system of wheelwork destined to obviate the difficulty of turning so large an instrument either by hand or a rope attached to the two ends of the axis, as at Washington and Vienna, owing to the amount of the friction. The eyepiece micrometers, as now constructed by the Repsolds, are commended for their rapid and convenient use. Amongst his general practical conclusions Prof. Newcomb expresses the opinion that in the mounting of instruments of the larger size, in order to secure necessary stiffness with the least weight, the axes should be hollow. He does not consider that it is worth while to attach friction-rollers to the declination axis, unless further experiment should show that they can be rendered more effective than in the Vienna equatorial. The old system of attaching a single finder to that side of the telescope which is opposite the declination axis, he remarks, is insufficient in the case of a large instrument, owing to the necessity of setting the opening in the dome not only to the telescope but to the finder, and suggests the desirability of adopting the plan in the Vienna instrument, which has two finders, the one above and the other below the telescope when in the meridian—a plan obviating all difficulty. The Report further explains the principle of the equatorial *coudé*, or elbow-shaped equatorial, of the Paris Observatory. The Strasburg meridian-circle, "commonly considered to embody the latest conceptions in astronomical mechanics," is noticed in some detail; Prof. Newcomb thinks a degree of stability has been secured in it which has never before been reached, and he was at much pains to obtain data for comparing the instrument with the meridian-circle at Washington; its general design he describes as similar to that of the great meridian-circle at Harvard College Observatory, which was constructed by Troughton and Simms of London. The reader must be referred to the Report for other particulars bearing upon meridian instruments.

THE ASPECT OF URANUS.—In a note communicated to the Paris Academy of Sciences on June 9, MM. Henry state that, observing on very fine nights with the 15-inch refractor, they have satisfied themselves of the existence of two gray belts, straight and parallel, and placed almost symmetrically with respect to the centre of the disk of Uranus, and that, by measures of their direction, they have found an inclination of about 41° to the direction of the orbits of the satellites; they assume that the planet's equator is in the direction of the belts. Astronomers will probably look for confirmation of such an anomaly to our larger instruments.

THE CONTINUITY OF THE PROTOPLASM THROUGH THE WALLS OF VEGETABLE CELLS

AMONG the numerous generalisations of modern botany there are perhaps few that promise to have more important consequences than the recent statements to the effect that the protoplasmic contents of the cells of plants are not entirely shut off from one another by the cell-walls, but that arrangements exist of such a kind that more or less delicate strands of protoplasm pass through from one cell to another, piercing the cell-walls either at numerous points at certain thinner spots, or simply here and there.

Th. Hartig in 1837 distinguished certain constituents of the bast of phanerogams which we now know as sieve-tubes. Investigated later by the same observer and by Mohl, Nägeli, Sachs, and Hanstein, the question as to whether the septa between the cylindrical constituents of these tubes are really perforated, or simply studded with thin pits, was set at rest by the demonstration that strands or cords of protoplasmic substance pass through definite pores or passages in the septa or cell-walls. This discovery then became common property, abundantly confirmed, and is now practically demonstrated by students in every properly conducted botanical laboratory: it remained somewhat isolated for many years, however.

In 1880 the botanical world was startled by Tangl's discovery that the cells of the endosperm of certain seeds (*Strychnos*, *Areca*, &c.) present a similar feature—that delicate filaments of protoplasm traverse the cell-walls through fine perforations, and so place the protoplasmic contents of the cells in direct continuity one with another.

In 1882 Gardiner showed that a similar continuity of the protoplasm exists between the cells of the motile organs of certain sensitive plants, and there can be no doubt that the communication thus established through the cell-walls is instrumental in causing the propagation from cell to cell of the stimulus which induces the movement. It thus becomes established that the cell-walls of plants can no longer be regarded as entirely separating off the contents of one cell from those of another; but that, in many cases at any rate, the idea of the individuality of the vegetable cell becomes as difficult to maintain as did that of animal cells after the first struggles which resulted in the overthrow of the old cell theory.

Since 1882, Gardiner has succeeded in extending his results, and has shown that the cells of numerous other parts of plants are in continuity in the same manner, by strands of protoplasm passing through the cell-walls. These researches are, moreover, confirmed by Russow for certain cells of the parenchyma of bast and medullary rays; and there seems little need of hesitation to accept generally the view that the cells of plants are not closed sacs as was formerly believed, but are provided with passages through their walls, through which fine filaments of protoplasm communicate. Such at least results from the observations so far, and especially those of Gardiner, on the endosperms of a large series of plants. It may now be stated, however, that this is not the only evidence to be quoted in support of the above generalisation. In addition to the observations of Nägeli, Pringsheim, and others, pointing out that the protoplasm frequently adheres to the cell-walls so closely at certain places that it may be pulled out into strands, or even break away, leaving portions on the walls, Gardiner has also made observations which confirm this, and which strongly favour the view that the protoplasmic strands are held fast at the points where they traverse the cell-walls. Bower has also observed similar phenomena in the withdrawal of the peripheral protoplasm in plasmolysis.

Moreover, it has been pointed out that in the case of cells with very thick walls, the thin pits are normally found to meet on opposite sides; the same is the case with the radiating strands in *Volvox*, and where two opposite strands reach the common cell-wall at different angles, they nevertheless meet at a point.

So far, however, there is no evidence to show whether the continuity of the protoplasmic strands is maintained from the earliest stages, or is established later. This, however, is a very important question in connection with this subject, since the answer to it will materially affect our views as to the nature of the cell. If the cell-walls produced in vegetative division are not complete septa, but membranes filling up the interstices between continuous strands of protoplasm, then the continuity of the protoplasm through the wall of vegetable cells is simply to be regarded as an expression of the fact that the entire plant or

organ is practically one whole—one mass of protoplasm cut up into chambers which communicate with one another, and bounded by a membrane on the exterior. If, on the other hand, the communications between the protoplasm of neighbouring cells are only established after a complete septum has been formed, then it may or may not be that the above view holds, —so far as the continuity of the protoplasm of mature cells is concerned, it affords no conclusive proof against the very generally accepted idea that the plant consists of cell units aggregated into colonies, tissues, &c.

Turning for a moment to certain investigations which throw light on this matter from totally different directions, it will be seen that there is much to be said for the view lately stated by Sachs, and first hinted at by Hofmeister, that a much closer relation of cell to cell exists than can be well explained by the theory that a plant is a sort of cell republic, consisting of aggregated cell units.

Strasburger's well-known investigations on the process of cell division have led to the remarkable and startling result that the septum or partition-wall, formed when a cell divides, is in general a solid membrane built up by the aggregation of certain particles (microsomes) which become arranged into a plate (the cell-plate) at the equator of the dividing mass of protoplasm. These microsomes are conducted to this equator, and there mobilised by certain delicate fibrillæ in the protoplasm; these fibrillæ form the well-known spindle-like figure, and are continuous across the equator. If the microsomes travel along the fibrillæ from either side, and are fitted together between them, it seems difficult to doubt that the continuity of the protoplasm observed later simply depends upon the persistence of this primitive continuity, and such appears to be the case.

The proof that the primitively continuous fibrillæ remain continuous throughout does not yet exist however; and although it is so likely, it cannot be forgotten that protoplasm possesses a marvellous power of boring through and dissolving even adult cell-walls, as is evident in the exit of zoospores or the entrance of parasites through cell-walls, the formation of pollen-grains, &c.

But we have not yet exhausted the evidence for the view that the continuity of the protoplasm through the cell-walls of fully developed organs exists from the first.

The investigations of Strasburger, Schmitz, and others, on the protoplasm and nucleus of vegetable cells, have yielded the results that, in the first place, many cells believed to be devoid of nuclei really possess these structures, and often in enormous numbers; and, secondly, that many cases of division occur where a delicate cell-wall is formed in the equatorial plane between the two dividing nuclei, but only to disappear later. In many other cases no recognisable septum is formed at all. The internodes of *Chara* and the zoosporangia of *Achlya* may be cited as examples. In *Vaucheria*, *Caulerpa*, &c., again, we have plants each of which is practically a single cell with numerous nuclei: these nuclei divide as the cell grows, but no cell-walls are formed —the plant remains "unicellular."

If in such cases a septum were formed each time a nucleus divides, the protoplasm of the *Vaucheria*, *Caulerpa*, &c., would become divided up into cells; and if the septum in each division were incomplete only in so far that it allowed the fibrillæ of protoplasm which carry and arrange the microsomes to remain continuous through it, we should have essentially the condition of things demonstrated by Hanstein, Tangl, and especially by Gardiner.

But it would in such a case be imperative to express the facts in accordance with the primitive state of affairs—the protoplasm of the hypothetical plant would be cut up into compartments or cells, communicating throughout. Now it is just this view which Sachs has lately brought forward so clearly and ably. A multicellular plant does not grow and become complex because it consists of numerous aggregated cells which increase and divide; but it becomes multicellular because it grows larger, and partition walls are placed in the mass partly for mechanical purposes, partly to insure physiological distribution of labour.

It is impossible, Sachs thinks, to hold the view that *Vaucheria*, *Caulerpa*, and such plants have arisen by the degradation of ancestors which formed cell-walls. It is also suggestive that the nuclei in such "unicellular" plants are more closely packed at the growing apex of the vesicle; for we may thus understand how the growing point of an organ with a single large apical cell only differs in degree from one with numerous small apical cells.

The consideration of all these matters leads to the conviction that the cell-theory so long taught may have to be modified even more than it has been during the last ten or twelve years; and that once more we are being driven back to that centre of all biological phenomena—the properties of protoplasm, multiple and various in degree and in kind as they are.

In conclusion, we cannot omit drawing attention to the improved and refined methods employed by the careful and skilled botanists of the younger school; and it is to be hoped that those who pass over the ground again will be at least equally well equipped. It is not only reagents that are necessary in such matters—critical power is indispensable as well as pure chemicals, as any one may convince himself by the study of the recent memoirs referred to, including the careful papers from Gardiner's hands. One more point may well be insisted upon here: the exhaustive study of a series of facts invariably brings them at length into relation with other facts, and where neither series is alone sufficient to base a scientific induction upon, converging groups of observations may result in the establishment of very important generalisations, leading to the recognition of still larger consequences. There can be no question of the intrinsic value of the observations on the continuity of protoplasm, apart from the information they give in connection with physiological matters; but it is certain that they gain immensely in scientific importance when looked at in the light afforded by recent discoveries as to the behaviour of the nucleus and protoplasm in cell division.

NATIONAL WORK AND HEALTH

THE work of the International Juries was formally inaugurated at the Health Exhibition on Tuesday by H.R.H. the Prince of Wales. The principal address was given by Sir James Paget, who chose as his subject "The Relation between National Health and Work," especially as it may be shown in a few of the many examples of the quantity of work which is lost to the nation either through sickness or through deaths occurring before the close of what may fairly be reckoned as the working time of life.

Sir James Paget went on to say:—I think it may be made clear that this loss is so great that the consideration of it should add largely to the motives by which all people may be urged to the remedy of whatever unwholesome conditions they may live in. It is a subject which is often in the minds of the real students of the public health, but the public itself is far too little occupied with it.

In view of the national health and welfare, the pattern healthy man is one who lives long and vigorously; who in every part of his life, wherever and whatever it may be, does the largest amount of the best work that he can, and, when he dies, leaves healthy offspring. And we may regard that as the healthiest nation which produces, for the longest time and in proportion to its population, the largest number of such men as this, and which, in proportion to its natural and accumulated resources, can show the largest amount and greatest variety of good work.

Here let me insert, as an interpretation clause, that in all this and what is to follow the word "man" means also "woman," and "he" also means "she"; and that when I speak of work I mean not only manual or other muscular work, but work of whatever kind that can be regarded as a healthy part of the whole economy of the national life. And I shall take it for granted that a large portion of all national welfare is dependent on the work which the population can constantly be doing; or, if I may so express it, that the greater part of the national wealth is the income from the work which is the outcome from the national health.

It is a common expression that we do not know the value of a thing till we have lost it; and this may be applied to the losses of work which are due to the losses of national health. There are very few cases in which these can be estimated with any appearance of accuracy; but I am helped to the best within our present reach by Mr. Sutton, the Actuary to the Registry of Friendly Societies. In his office are the returns, for many years past, of the sickness and mortality among the members of a very large number of these Societies; and, among other things, there is recorded the number of days on which each member, when "off work" on account of sickness, received money from his Society. Hence Mr. Sutton can estimate, and this he has been so good as to do for me, the average number of days' sickness and consequent loss of work among several hundred thousands of the workmen and others who are members of these Societies. From the entire mass of these returns, he deduces that the

average number of days' sickness, per member, per annum, is very nearly a week and a half; and this agrees, generally, with the estimates made in other Societies by Mr. Neison and others. But the averages thus obtained include the cases of members of all ages, and among them many cases of chronic sickness and inability to work during old age. In order, therefore, to get a better idea of the actual annual loss of work through sickness, he has taken the published experience of the members of the large group of Friendly Societies known as the Manchester Unity of Odd Fellows; and then, on the fair assumption that the rates of sickness of the whole population during the working years of life would not be far different, he has calculated the following tables, showing the average annual rates of sickness of each person, enumerated in the Census of 1881, as living between the ages of 15 and 65:—

Ages.	Number of Males: Census of 1881 (England and Wales).	Weeks' Sickness per annum, according to the experience of the Manchester Unity.	Average Sickness per individual per annum (in weeks).
15–20	1,268,269	844,428	·666
20–25	1,112,354	820,183	·737
25–45	3,239,432	3,224,134	·995
45–65	1,755,819	4,803,760	2·736
All ages from 15–65	7,375,874	9,692,505	1·314

Ages.	Number of Females: Census of 1881.	Weeks' Sickness per annum, according to the experience of the Manchester Unity.	Average Sickness per individual per annum (in weeks).
15–20	1,278,963	851,701	·666
20 25	1,215,872	896,685	·737
25–45	3,494,782	3,476,146	·995
45–65	1,951,713	5,368,229	2·751
All ages from 15–65	7,941,330	10,592,761	1·334

Briefly, it appears from these tables that the average time of sickness among the male population during the working years is a small fraction more than 9 days each in each year—and that among the female population it is yet a small fraction more; the excess arising from the larger proportion of persons at the later ages. The result is that among males there is a loss of 9,692,505 weeks' work in every year, and among females a loss of 10,592,761 weeks. Thus we may believe that our whole population between 15 and 65 years old do, in each year, 20,000,000 weeks' work less than they might do if it were not for sickness. The estimate is so large that it must, on first thoughts, seem improbable; but on fair consideration I believe it will not seem so. For the members of the Manchester Unity who are in the working time of life the reckoning is certainly true, and it is founded on the experience of between 300,000 and 400,000 members. In respect of health they may represent the whole population at least as well as any group that could be taken. They are not very strictly selected, they are not picked lives, yet they are such as are able, when they are in health, to earn good wages or good salaries, and, as their prudence in joining this association shows, they are comparatively thrifty and careful persons. They do not, at all events, include many habitual drunkards, cripples, or utter invalids, or those who, through natural feebleness or early disease, or mere profligacy, cannot earn enough to become members or maintain themselves in membership. Neither do they include many of the insane or imbecile and idiotic, of whom there are, in our population, nearly 70,000 doing no work, and losing not less than 3,500,000 of weeks' work in the year.

It would be tedious to tell the grounds on which the estimate may be deemed too high, for just as many and as good could be told on which it might be deemed too low. And it is rather more than confirmed by some estimates of the annual sickness in other and very different groups of persons.

In the Army, at home, the average number of days' sickness in each year is, for each soldier, about 17; and as the number of the troops in the United Kingdom is more than 80,000, we have here a loss of about 200,000 weeks' service in each year.

In the Navy, on the home stations, the average number of days' sickness in each year has been in the last five years for each man nearly 16; so that for the total of about 20,000 men there is a loss of 45,000 weeks' service in each year.

The amount of sickness in the services thus appears much higher than in the Friendly Societies. This is due, in great part, to the fact that a soldier or a sailor is often put off duty for a day or two for much less illness than that for which a civilian would "go on his club." Still, the one estimate may confirm the other; for the sickness in the Army and Navy is that of picked men, who were selected for the services as being of sound constitution, and who are in what should be the best working years of life: and if it includes many cases of sickness for only a day or two, it excludes nearly all cases of more than a few months, such as make up a heavy proportion of the average sickness in the Friendly Societies and in the general population.

And I may add that the estimate from these Societies, that 9 days in the year may justly be thought a fair estimate of the working time lost by sickness, is confirmed by the records of sickness among the 10,000 members of the Metropolitan Police Force; for among these, including cases of long illness such as are also in the Societies, the average is more than 9 days in the year.

I think, then, that we cannot escape from the reasons to believe that we lose in England and Wales, every year, in consequence of sickness, 20,000,000 of weeks' work; or, say, as much work as 20,000,000 of healthy people would do in a week.

The number is not easily grasped by the mind. It is equal to about one-fortieth part of the work done in the year by the whole population between 15 and 65 years old. Or, try to think of it in money. Rather more than half of it is lost by those whom the Registrar-General names the domestic, the agricultural, and the industrial classes. These are rather more than seven millions and a half in number, and they lose about 11,000,000 of weeks; say, for easy reckoning, at a pound a week; and here is a loss of 11,000,000*l.* sterling from what should be the annual wealth of the country. For the other classes, who are estimated as losing the other 9,000,000 weeks' work, it would be hard and unfair to make a guess at the loss in any known coin; for these include our great merchants, our judges and lawyers, and medical men, our statesmen and chief legislators; they include our poets, and writers of all kinds, musicians, painters, and philosophers; and our Princes, who certainly do more for the wealth and welfare of the country than can be told in money.

Before I speak of any other losses of work or of wealth due to sickness, permit me, as in parenthesis, to point out to you how very imperfectly their losses are told or even suggested by our bills of mortality. These, on which almost alone we have to rely for knowing the national health—these tell the losses of life; and more than misery enough they tell of; but to estimate rightly the misery of sickness and the losses of all but life that are due to it, we need a far more complete record than these can give.

Take, for example, such a disease as typhoid fever—that which Mr. Huxley has rightly called the scourge and the disgrace of our country. It has of late destroyed in England and Wales, among persons in the working time of life, nearly 4000 in the year. Its mortality is about 15 per cent., so that if in any year 4000 die of it, about 23,000 recover from it. Of these the average length of illness is, on the authority of Dr. Broadbent, about ten weeks. Here, therefore, from one disease alone, and that preventible, we have an annual loss of 230,000 weeks' work, without reckoning what is lost with those who die. And the same may be said of nearly all the diseases that are most prominent in the bills of mortality. The record of deaths, sad as it is, tells but a small part of the losses of happiness and welfare that are due to sickness. It is as if, in a great war, we should have a regular return of the numbers killed, but none of the numbers sick and wounded, though these, more than the killed, may determine the issue of the war.

Let me now tell of another loss of work and of money through sickness and early death. In all the estimates I have yet referred to, no account is taken of those who are ill or die before they are 15 years old. They are not reckoned as in the working-time of life, though in some classes many thousands of them are. [In the domestic, agricultural, and industrial classes of the Registrar-General nearly half a million of them are included.] And yet the losses of work due to sickness among children must be very large. Consider the time which might be spent in good productive work, if it were not spent in taking care of them while they are ill. Consider, too, the number of those who, through disease in childhood, are made more susceptible of disease in later life, or are crippled, or in some way permanently damaged; such as those who become deaf in scarlet

fever, or deformed in scrofula or rickets, or feeble and constantly invalid, so that they are never fit for more than half work or work which is only half well done. These losses cannot be counted, but they must be large; and there are others more nearly within reckoning; the losses, namely, which are due to the deaths of those who die young. It may justly be said that all that they have cost during their lives is so much money sunk; so much capital invested and lost. If they had lived to work, their earnings would have been more than sufficient to repay it; but they have died, and their cost is gone without return. The mortality of children under 15 in 1882 was nearly a quarter of a million: what have they cost? If you say only 8*l*. a piece, there are more than 2,000,000*l*. sterling thus lost every year. But they have cost much more than this, and much more still is lost by the loss of the work they might have lived to do.

I will add only one more illustration of these losses, which is always suggested by looking at tables of mortality. The deaths of persons between 25 and 45 years old, that is during what may be deemed the 20 best working years of life, are annually between 60,000 and 70,000; in 1882 they were 66,000. Think, now, of the work lost by these deaths; and of how much of it might have been saved by better sanitary provisions. If one looks at the causes of their deaths, it is certain that many might have been prevented, or, at least, deferred. Say that they might have lived an average of 2 years more; and we should have had in this year and last an increase of work equivalent to that of at least 6,000,000 weeks; as much, in other words, as 6,000,000 people could do in one week.

More instances of losses of work by sickness and premature death might easily be given, but not easily listened to in this huge hall. Let these suffice to show something of our enormous annual loss, not only of personal and domestic happiness—that is past imagining—but of national power and wealth. Surely we ought to strive more against it.

But, some may ask, can these things be prevented? are they not inevitable consequences of the manner of life in which we choose or are compelled to live? No; certainly they are not. No one who lives among the sick can doubt that a very large proportion of the sickness and the loss of work which he sees might have been prevented; or can doubt that, in every succeeding generation, more may be averted, if only all men will strive that it may be so.

Let me enumerate some of the chief sources of the waste as they appear to one's self in practice, or as one looks down a table of mortality.

Of the infectious fevers, small-pox might be rendered nearly harmless by complete and careful vaccination. Typhus and typhoid, scarlet fever and measles, might, with proper guards against infection, be confined within very narrow limits. So, probably, might whooping-cough and diphtheria.

Of the special diseases of artisans there are very few of which the causes might not be almost wholly set aside. Of the accidents to which they are especially liable the greater part, by far, are due to carelessness.

Of the diseases due to bad food and mere filth; to intemperance; to immorality; in so far as these are self-induced, they might, by self-control and virtue, be excluded. And with these, scrofula, rickets, scurvy, and all the widespread defects related to them, might be greatly diminished.

It can only be a guess, but I am sure it is not a reckless one, if I say that of all the losses of work of which I have spoken, of all the millions of weeks sadly spent and sadly wasted, a fourth part might have been saved, and that, henceforth, if people will have it so, a still larger proportion may be saved.

We may become the more sure of what may be done by looking at what has been done already. Let me show some of it; it will be a relief to see something of the brighter side of this picture.

In a remarkable paper lately read before the Statistical Society, Dr. Longstaff says:—"One of the most striking facts of the day, from the statistician's point of view, is the remarkably low death-rate that has prevailed in this country during the last eight years." In these years the annual death-rate has been less than in the previous eight years, in the proportion of two deaths to every 1000 persons living. The average annual number of deaths has been 50,000 less in the last than in the previous eight years. Doubtless many things have contributed to this grand result, and it is not possible to say how much is due to each of them; but it would be unreasonable to doubt that the chief good influence has been in all the improved means for the care of health which recent years have produced. This is made nearly certain by the fact that the largest gains of life have been in the diminution of the deaths from fever, and of the deaths in children under 15 years old; for these are the very classes on which good sanitary measures would have most influence.

The annual number of deaths from typhus, typhoid, and the unnamed fevers, has been about 11,000 less than it was about 20 years ago. The annual number of deaths of children under 5 years old has been about 22,000 less than it was; and that of children between 5 and 15 has been upwards of 8,000 less.

These are large results, and though they tell of only deaths, yet they bear on the chief subject I have brought before you—the working power of the nation; for, however much of the average we might assign to improved methods of medical treatment of fever, yet the diminished number of deaths means a very large diminution in the total number of cases. The deaths during the working years of life were 6,500 less; and, this being so, we may hold that, if the average mortality was, say, 25 per cent., the diminution in the total number of cases must have been at least 25,000; and if we may believe, as before, that each of these involved ten weeks of sickness, we have, in these fevers alone, a clear saving of 185,000 weeks' work in every year.

And so with the diminution of the mortality among children, there must have been a greater diminution in the number of costly and work-wasting illnesses, and a large saving of money that would otherwise have been sunk. And not only so: but many of the children saved in the last eight years will become bread-winners or care-keepers; and who can tell what some of them will become? or what the world would have lost if it had lost them?

Let me add only one more reckoning. In a paper last year, at the Statistical Society, Mr. Noel Humphreys said "that if the English death-rate should continue at the low average of the five years 1876-80, the mean duration of male life in this country would be increased by two years, and that of female life by no less than 3·4 years as compared with the English Life-table." And he showed further that "among males 70 per cent. and among females 65 per cent. of this increased life would be lived between the ages of 20 and 60 years, or during the most useful period."

I should like to be able to tell the value in working-power of such an addition to our lives. It is equal to an addition of more than 4 per cent. to the annual value of all the industry, mental and material, of the country.

But some will say—admitting that it is desirable, seeing how keen the struggle for maintenance already is, can more than this be done? and the answer may be and must be, much more. In this, as in every case of the kind, every fruit of knowledge brings us within reach of something better. While men are exercising the knowledge they possess, they may be always gaining more. This Exhibition has scores of things which are better helps to national health than those of the same kind which we had twenty years ago, and with which the gains already made were won. If I were not in near official relation with the jurors I would name some of them: there are truly splendid works among them.

But do not let me seem to disparage the past in praising the present. It is difficult to speak with gratitude enough of what has been done, even though we may now see ways to the yet better.

Any one who has studied the sources of disease during the last thirty years can tell how and where it has been diminished. There is less from intemperance, less from immorality; we have better, cheaper, and more various food; far more and cheaper clothing; far more and healthier recreations. We have, on the whole, better houses and better drains; better water and air, and better ways of using them. The care and skill with which the sick are treated in hospitals, infirmaries, and even in private houses, are far greater than they were; the improvement and extension of nursing are more than can be described; the care which the rich bestow on the poor, whom they visit in their own homes, is every day saving health and life; and, even more effectual than any of these, is the work done by the medical officers of health and all the sanitary authorities now active and influential in every part of the Kingdom.

Good as all this work has been, we may be sure it may become better. The forces which have impelled it may still be relied on. We need not fear that charity will become cool, or

philanthropy inactive, or that the hatred of evil will become indifference. Science will not cease to search for knowledge, or to make it useful when she can; we shall not see less than we do now, and here, of the good results of enterprise and rivalry, and of the sense of duty and the sorrow for shame that there should be evil in the land.

What more, then, it may be asked, is wanted? I answer, that which I have tried to stir: a larger and more practical recognition of the value and happiness of good national health; a wider study and practice of all the methods of promoting it; or, at least, a more ready and liberal help to those who are striving to promote it. In one sentence, we want the complete fulfilment of the design of this Exhibition, with all the means towards health and knowledge that are shown in it, and with its handbooks, lectures, conferences, and the verdicts of its juries.

We want more ambition for renown in health. I should like to see a personal ambition for renown in health as keen as is that for bravery, or for beauty, or for success in our athletic games and field-sports. I wish there were such an ambition for the most perfect national health as there is for national renown in war, or in art or commerce. And let me end soon by briefly saying what I think such health should be.

I spoke of the pattern healthy man as one who can do his work vigorously wherever and whatever it may be. The union of strength with a comparative indifference to the external conditions of life, and a ready self-adjustment to their changes, is a distinctive characteristic of the best health. He should not be deemed thoroughly healthy who is made better or worse, more or less fit for work, by every change of weather or of food; nor he who, in order that he may do his work, is bound to exact rules of living. It is good to observe rules, and to some they are absolutely necessary, but it is better to need none but those of moderation, and, observing these, to be able and willing to live and work hard in the widest variations of food, clothing, and all the other sustenances of life.

And this, which is a sign of the best personal health, is essential to the best national health. For in a great nation, distributed among its people, there should be both muscular and mental powers suited to the greatest possible variety of work. No form or depth of knowledge should be beyond the attainment of some among them; no art should be beyond its reach; it should be excellent in every form of work. And, that its various powers may have free exercise and influence in the world, it must have, besides, distributed among its people, abilities to live healthily wherever work must be or can be done.

Herein is the essential bond between health and education; herein is one of the motives for the combination of the two within the purpose of this one Exhibition; I do not know whether health or knowledge contributes most to the prosperity of a nation; but no nation can prosper which does not equally promote both: they should be deemed twin forces, for either of them without the other has only half the power for good that it should have.

It is said, whether as fact or fable, that the pursuit of science and of all the higher learning followed on the first exercise of the humanity which spared the lives of sick and weakly children; for that these children being allowed to live, though unfit for war or self-maintenance, became thinkers and inventors. But learning is not now dependent upon invalids; minds are not the better now for having to work in feeble bodies; each nation needs for its full international influence both health and knowledge, and such various and variable health that there should be few places on earth or water in which some of its people cannot live, and multiply, and be prosperous.

If, therefore, we or any other people are to continue ambitious for the extension of that higher mental power of which we boast, or for the success of the bold spirit of enterprise with which we seek to replenish the earth and subdue it; if we desire that the lessons of Christianity and of true civilisation should be spread over the world, we must strive for an abundance of this national health, tough, pliant, and elastic, ready and fit for any good work anywhere.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The Senior Wrangler, Mr. W. F. Sheppard, scholar of Trinity College, is a native of Australia; the Second Wrangler, Mr. W. P. Workman, also a scholar of Trinity, is the son of a Wesleyan minister.

The Natural Sciences Tripos, Part 1, contains the names of fifty-three men, of whom thirteen are placed in the first class; in addition six are allowed an ordinary degree, and six are excused the general examination. Two ladies attained a first class, four a second, and one a third.

In the Natural Sciences Tripos, Part 2, the first class includes the names of Messrs. Adami (Physiology) Christ's College; Chree (Physics), King's; Green (Botany, Physiology), Trinity; Head (Physiology), Trinity; Laurie (Chemistry), King's; Phillips (Botany), St. John's; Shipley (Zoology), Christ's; and Threlfall (Chemistry, Physics), Caius. The subjects mentioned are those for distinction in which the candidates are placed in the first class.

Mr. C. Potter will give lectures on Systematic Botany with field excursions and practical work, in the long vacation, beginning July 8.

SOCIETIES AND ACADEMIES

LONDON

Mathematical Society, June 12.—Prof. Henrici, F.R.S., president, in the chair.—Mr. G. S. Ely, Fellow of the Johns Hopkins University, Baltimore, was elected a member.—The chairman announced that the Council had awarded the first De Morgan gold medal to Prof. Cayley, F.R.S.—A note on the induction of electric currents in a cylinder placed across the lines of magnetic force, by Prof. H. Lamb, was read in abstract.—Mr. J. Hammond gave some results of a paper which is shortly to appear in the *American Journal of Mathematics*.

Linnean Society, June 5.—Wm. Carruthers, F.R.S., vice-president, in the chair.—Messrs. J. Starkie Gardner, F.G.S., and J. H. Leech were elected Fellows of the Society.—Mr. J. Harris Stone exhibited and made remarks on specimens and photographs, viz. portion of the wood and of a remarkable wart (as large as a cocoa-nut) from the famous dragon-tree, *Dracæna draco*, of the Canaries; photograph of the young dragon-tree planted by the Marquesa de Sawyal, and now growing on the site of the old celebrated tree of Oratova; photograph of the dragon-tree of Icod-de-los-Vinos in Teneriffe; and a photograph of the Peak of Teneriffe, showing how the "Retana" grows on the Cañadas.—There was shown, on behalf of Mr. R. Morton Middleton, a small branch of *Cotoneaster microphylla* grown at Castle Eden, Co. Durham, and a good example of fasciation in this plant.—Dr. R. C. A. Prior afterwards drew attention to specimens of the rare *Potentilla rupestris* from Craig Breidhin, Montgomeryshire, and of *Rumex sanguineus*, from the neighbourhood of Bristol, both freshly gathered by Mr. T. Bruges Flower, F.L.S.—A paper by Mr. G. Claridge Druce was read, in which he describes a new variety of *Melampyrum pratense*, L., and which he suggests should be known as var. *hians*.—Prof. J. Martin Duncan read a paper on a new genus of recent Fungida allied to the fossil form *Micrabacia*; the genus being based on a specimen of coral obtained from shallow water in the Corean Sea.—A communication was made by Mr. Arthur R. Hunt, on the influence of wave-currents on the fauna inhabiting shallow seas. The author refers to various physical data, among others quoting Prof. Stokes and Mr. T. Stevenson, the latter stating that a current of 0·6819 of a mile per hour will carry forwards fine gravel, and that of 1·3638 roll along pebbles an inch in diameter. From this and other facts Mr. Hunt argues that wave-currents do materially influence the marine fauna inhabiting shallow water, not only those of the tidal strand, but likewise those inhabiting the deeper sea-bottom. He adduces instances of animals living among or on rocks, and of those frequenting sand or other deposits, enumerating species of star-fish, mollusks, shrimps, crabs, and fish. He says that even the flat-fishes (Pleuronectidæ) seem to have changed their original forms and habits for the purpose of being able to live in shallow waters agitated by waves. Referring more particularly to species of *Cardium*, he endeavours to show how, under the influence of wave-currents, the variation of species may be promoted and even their local extinction brought about.—A paper was read, on the Longicorn Beetles of Japan, by Mr. H. W. Bates. In a former paper (in 1873), on the same subject, the author treated of 107 species, but now adds many new genera and 129 more species, or a total of 236 specific forms as at present known to belong to the Japanese fauna. This great accession is due to the later collections of Mr. Geo. Lewis, who made a second

visit to the islands in 1880–81. Mr. Bates, reasoning from this fresh material, is inclined to modify his previously-stated views as to the predominance of a supposed tropical element in the Longicorn group in question; the relative number of absolutely new genera now turning the scale in favour of Palæarctic or Nearctic affinities.—The last zoological communication taken was on three new species of *Metacrinus*, by P. Herbert Carpenter, with note on a new *Myzostoma*, by Prof. von Graff. Mr. Carpenter describes *Metacrinus rotundus* from Japan, dredged there by Dr. Doderlein of Strasburg, and *M. superbus* and *M. stewarti*, two remarkable forms obtained by the Telegraph Company on picking up a cable near Singapore. The *Myzostoma cirripedium* was found on the Japan Crinoid.

Chemical Society, June 5.—Dr. Perkin, F.R.S., president, in the chair.—It was announced that a ballot for the election of Fellows would take place at the next meeting.—The following papers were read:—On β-napthaquinone, by C. E. Groves. In a preliminary notice read before the Society some time since (*Chem. News*, xliii. 267) the author mentioned that he had carefully repeated some experiments of Liebermann. In the present paper full details are given of the preparation of amido-β-naphthol hydrochloride from β-naphthol orange by reduction with stannous chloride and with alkaline sulphides. This reaction is very inferior in simplicity and economy to the process originally proposed by Stenhouse and the author. Several improvements in the original process are suggested, and the author gives an account of some products obtained by the action of reducing agents on the nitroquinone.—On a by-product of the manufacture of aurin (part ii.), by A. Staub and Watson Smith. The authors have prepared a perfectly pure specimen of this product, phenylorthooxalic ether; they conclude that it plays no part as an intermediate product in the formation of aurin. Analogous compounds with α- and β-naphthols were prepared, but no compound with resorcinol could be obtained.—On calcium hydrosulphides, by E. Divers and Tetsukichi Shimidzu. When hydrogen sulphide is passed through milk of lime, the lime dissolves; by adding more lime, a solution is finally obtained, which, after decantation and cooling, deposits colourless prismatic crystals of the hydrosulphide; by the action of water on this body, calcium hydroxyhydrosulphide is formed. The authors find that hydrogen sulphide decomposes calcium carbonate. They have also studied calcium monosulphide and the formation of the thiosulphate from the hydrosulphide and the pentasulphide.

Anthropological Institute, May 27.—Prof. Flower, F.R.S., president, in the chair.—The election of F. C. J. Spurrell was announced.—Mr. H. O. Forbes read a paper on the Kubus of Sumatra. The Kubus are a nomadic race inhabiting the central parts of Sumatra. In their wild state they live in the deep forest, making temporary dwellings, consisting of a few simple branches erected over a low platform to keep them from the ground, and thatched with banana or palm leaves. They are extremely timorous and shy, so that it is a very rare thing for any of them to be seen, and if suddenly met in the forest by any one not of their own race, they drop everything and flee away. They cultivate nothing, and live entirely on the products of the chase. Their knives and the universal spear with which they are armed are purchased from the Malays, with whom they trade. They are of a rich olive-brown colour, and their jet-black hair, apparently far less straight than that of the village Malays, was always in a dishevelled state and in curls. The average height of the males was about 1·59 m. and that of the females 1·49 m.—Dr. Garson read a paper on the osteology of the Kubus.—Mr. Theodore Bent read some notes on prehistoric remains in Antiparos, and exhibited several specimens of pottery, some rudely carved marble figures, and a skull, from cemeteries in that island.

Institution of Civil Engineers, May 20.—Sir J. W. Bazalgette, C.B., president, in the chair.—The paper read was on the passage of upland water through a tidal estuary, by W. R. Peregrine Birch, M.Inst.C.E.

CAMBRIDGE

Philosophical Society, May 12.—Mr. Glaisher, president, in the chair.—The following were elected Honorary Members:—On the Foreign List—A. Baeyer, Professor of Chemistry at Munich; Anton Dohrn, Director of the Zoological Station at Naples; Carl Gegenbaur, Professor of Comparative Anatomy in the University of Heidelberg; G. Mittag Leffler, Professor of Mathematics in Stockholm; E. F. W. Pflüger, Professor of Physiology in the University of Bonn; Gustav Quincke, Professor of Physics in the University of Heidelberg; H. A. Rowland, Professor of Physics in the Johns Hopkins University, Baltimore, U.S.A.; Julius Sachs, Professor of Botany in the University of Würzburg; H. G. Zeuthen, Professor of Mathematics in Copenhagen. On the Home List—R. Stawell Ball, Astronomer-Royal for Ireland; W. T. Thiselton Dyer, Assistant Director of the Royal Gardens, Kew; J. Whitaker Hulke, ex-President of the Geological Society.

May 26.—Mr. Glaisher, president, in the chair.—Prof. E. Ray Lankester was elected an Honorary Member. Mr. S. L. Hart, St. John's College, was elected a Fellow.—The following communications were made:—On some irregularities in the values of the mean density of the earth as determined by Baily, by Mr. W. M. Hicks. The author showed that the numbers obtained by Baily for the mean density of the earth depended on the temperature of the air at which the different observations were made; and he exhibited a table showing that as the temperature increased from 40° F. to 60° F. the deduced mean densities fell continuously from 5·734 to 5·582. He considered several possible causes of error, but showed that they were either inadequate to explain the irregularities, or tended in the opposite direction. The only further suggestion that occurred to him was that Baily's personal equation was a function of the temperature, leading him, as his temperature rose, to estimate distances more liberally.—On some physiological experiments, by Dr. Gaskell.—On a method of comparing the concentrations of two solutions of the same substance but of different strength, by Mr. A. S. Lea.—On the many-layered epidermis of *Clita nobilis*, by Mr. W. Gardiner.—On the possible systems of jointed wickerwork and their degrees of internal freedom, by Mr. J. Larmor.

DUBLIN

University Experimental Science Association, June 3.—Dr. Tarleton, F.T.C.D., in the chair.—G. F. Fitzgerald, F.T.C.D., F.R.S., on Prof. Osborne Reynolds' mechanical illustrations of heat-engines.—J. Joly, B.E., on the eruption of Krakatoa.—The Cambridge Instrument Company's reflecting galvanometer was exhibited by Prof. Fitzgerald, and a portable calorimeter designed for approximately determining the specific heats of minerals, by J. Joly.—An apparatus for determining the latent heat of vaporisation was exhibited by F. Trouton. The chief gain in the use of the apparatus is, that to effect a determination by its means it is not requisite to know either the boiling-point of the liquid or the specific heat of the body in either the liquid or gaseous condition. Both of these are very irregular and extremely difficult to determine at temperatures approaching the boiling-point. The use of calorimeters is also avoided, often a source of serious error. In the vessel in which the liquid is placed there is a spiral of platinum or other substance unattacked by the liquid. On passing a current of electricity (the difference in potential being insufficient to decompose the body if a compound) through the spiral, heat is generated, and the liquid vaporised if at the boiling-point. According as the body is vaporised it is conducted away to a condenser, collected, and weighed. All sensible loss of heat is prevented by surrounding the vessel by a larger one full of vapour obtained by boiling some of the liquid itself in the bottom of the outside vessel under the same pressure as in the inner one; so that, if in any experiment the weight is determined of the liquid vaporised while a known quantity of electricity passes, the heat required to vaporise unit weight of the body can be deduced, the resistance of the spiral being also known. As the electrical measurements are difficult to make sufficiently accurate, it is simpler to compare the latent heat of the body with that of a liquid of which the latent heat is known. This may be easily effected by employing a second apparatus similar to the first, in which the liquid taken as the standard (say water) is put. The same current is passed through both spirals, so that the ratio of the latent heats may be deduced on weighing the quantities vaporised, if the ratio of the resistances of the spirals is known. This, if both liquids boil at nearly the same temperature, may be obtained by a previous experiment where one of the bodies is put into both apparatuses, the ratio of the resistances being that of the weights of the substance to be vaporised.

EDINBURGH

Mathematical Society, June 13.—Mr. A. J. G. Barclay, vice-president, in the chair.—Mr. William Peddie read a paper,

illustrated by models, on the graphical representation of physical properties; and Mr. David Traill one on geometry from first principles.

PARIS

Academy of Sciences, June 9.—M. Rolland, president, in the chair.—Remarks on the apparent contour of the planet Venus, based on the study of the photographic plates obtained at Puebla during the recent transit of Venus, by MM. Bouquet de la Grye and Arago.—Note on heavy ordnance in connection with the large gun (16 cm.) lately supplied to the Spanish Government by the Société des Forges et Chantiers de la Méditerranée, by M. Dupuy de Lome.—Memoir on the presence of manganese in plants and animals, and on the part played by this substance in the animal system, by M. E. Maumené. Tea and tobacco are found to contain the largest quantities of metallic manganese, which is on the whole injurious to animals, and constantly rejected by them, hence it should no longer be employed medicinally.—On the aspect of Uranus and the inclination of its equator, as observed at the Paris Observatory during the first days of the present year, by MM. Paul and Prosper Henry.—Note on the symmetrical functions of the differences in the roots of an equation, by M. J. Tannery.—Description of a dynamo-electric machine on a new principle, a model of which has been constructed by MM. A. Damoiseau and G. Petitpont. For this engine it is claimed that it does double the work of those now in use.—On the property of silver to absorb oxygen gas at high temperatures, by M. L. Troost.—Note on the action of the sulphuret of copper on the sulphuret of potassium, by M. A. Ditte.—On the solubility of the bromides, iodides, and chlorides of potassium, sodium, calcium, and other halogenous salts, by M. A. Etard.—Observations on some colloidal substances, by M. E. Grimaux.—Synthesis of pyridic hydrides, results of two years' researches with β-lutidine and β-collidine (boiling at 196° C.), derivatives of cinchona and brucine, by M. Oechsner de Coninck. These somewhat incomplete results are now published in consequence of the remarkable facts recently disclosed by MM. Hofmann and Ladenburg.—On tribenzoylmesitylene, by M. E. Louise.—On crystallised colchicine, by M. A. Houdès.—Experiments on manure artificially prepared with a view to determining the amount of loss of nitrogen sustained during the process of fermentation, by M. H. Joulie. The loss of nitrogen was found to be about 20 per cent., a proportion inferior to what takes place in practice.—Note on the minerals associated with the diamond in the newly-discovered diamantiferous district of Salobro, province of Bahia, Brazil, by M. H. Gorceix.—Anatomy of the Echinoderms; on the organisation of the Comatules, by M. Edm. Perrier.—On the constitution of the Echinoderms, by M. C. Viguier.—Objections to the theory that the Sahara was a marine basin during the Quaternary period, by M. G. Rolland. From more recent surveys in various parts of this region the author concludes that since the Tertiary period the Sahara was mainly dry land, while at the close of the Miocene all North Africa had been upheaved, and since then during the Pliocene and Quaternary the South Mediterranean coast-line has undergone no important modifications.—On the lesions of the nerve-ducts of the spinal marrow in sclerotic affections, by M. J. Babinski.—M. Jamin was elected Perpetual Secretary in the Section of Physical Sciences in place of the late M. Dumas.

BERLIN

Physical Society, May 23.—Prof. H. W. Vogel reported on the final practical results of his researches conducted for many years on the means of photographing coloured objects in their natural shades. Sensitive plates are known to be affected only by the more refrangible rays, the less refrangible remaining inoperative. Hence, of coloured objects quite unnatural pictures are obtained, even the darkest shades of blue appearing as white; yellow and red, however bright and dazzling, as black; and so on Starting from the idea that the sensitive collodium is affected only by such rays as are absorbed by it, Prof. Vogel had years ago been occupied with the attempt to render his plates sensitive to less refrangible rays, by alloying the silver coating with a substance capable of absorbing these rays. The results corresponded at once with this *a priori* assumption. In fact, plates so prepared invariably produced an effect in the solar spectrum wherever the absorption bands of the alloy were found. It was impossible, however, to obtain like results with artificial colours. Many colouring substances which, when blended with the collodium, beautifully reproduced the yellow of the solar spectrum, were ineffective against the artificial and infinitely fainter yellow of painters. Prof. Vogel was induced constantly to resume these attempts by the progress made both in the preparation of photographic appliances and in the discovery of new organic substances possessing a power of absorption more intense and lying nearer to the yellow of the spectrum. He has thus at last succeeded in obtaining in eosine, and more especially its various derivatives, colouring substances which scarcely possess more than a broad absorption band in the yellow, and which led to the desired result. When these bodies were mixed in due proportion with the dry gelatine plates, the yellow of the coloured objects already appeared quite clear on the photograph; but the blue was still always brighter. No satisfactory result was obtained until Herr Vogel had inserted between the object and the camera a yellow glass, which partly absorbs the blue rays while leaving the yellow unimpaired. He now obtained photographs in which the blue, as well as the green and yellow, and partly even the red parts of the coloured objects, presented to the observer's eye the same vivid effects as the original. A series of photographs exhibited by Herr Vogel side by side with the original pictures attest the good results with which this method may be carried out in practice.—Prof. Landolt referred to the controversy between MM. Pasteur and Jungfleisch, the former of whom had obtained from the optically inactive racemic acid dextro-gyrate tartaric acid by the culture of Penicillium. This he explained by supposing that the mould assimilates the other constituent of the inactive racemic acid, that is, the lævo-gyrate tartaric acid, leaving the other constituent over, whereas Mr. Jungfleisch accounts for the elimination of the dextrogyrate tartaric acid simply by its greater solubility. In support of Pasteur's view Prof. Landolt now adduced the experiment with amygdalic acid made last year by Dr. Lewkowitsch in his laboratory. Inactive amygdalic acid was by him, also by means of Penicillium, converted into dextro-gyrate amygdalic acid, which, jointly with the lævo-gyrate amygdalic acid formed from amygdaline, constituted inactive amygdalic acid, such as is obtained from prussic acid. Herr Landolt further reported that in his laboratory it had recently been demonstrated that tyrosine and leucine are optically active. Hence, according to the still unshaken theory of van t'Hoff, these substances must contain unsymmetrically united atoms of carbon.

SCIENCE AND THE WOOLWICH AND SANDHURST EXAMINATIONS

IT will be known to most readers of NATURE that after 1884 considerable changes will be made in the various subjects in the examinations for admission to Sandhurst, and it is generally understood that an extension of similar changes to the examination for Woolwich is in contemplation. When these changes were announced, those interested in the matter at once saw that one of their chief effects would be to greatly discourage science teaching in our schools, &c., in consequence of the extremely low marks allotted to it under the new scheme. Representations were made on the subject at the War Office by the President of the Royal Society, and subsequently it was stated in the House of Lords, in reply to a question put by Lord Salisbury, that the final position of the subjects is still under consideration. As there is every reason to suppose that the object of the War Office authorities is to secure as good an examination as possible, and as they can have no possible reason for wishing to discourage scientific candidates only because they are scientific, it would seem that the present is a favourable opportunity for bringing the subject into public notice. The following are perhaps the most important points in connection with it:—

1. How far the choice of subjects made by the candidates has hitherto been affected by the marks allotted to them, and hence in what degree the new regulations or any similar regulations will influence science studies in our public schools.

2. How far it is true that science subjects have been good (?) cram subjects, since from the discussion in the House of Lords it appears to be considered by the War Office authorities that they have been good cram subjects.

3. To what extent the subjects examined and their grouping is at present satisfactory, and in what respects they would be better for amendment.

4. Whether the standard of the examination is, as has been urged by some, too high.

In the consideration of 1 and 2 the statistics of past examinations will give much help; 3 and 4 are, no doubt, to a greater degree matters of opinion.

I. As the result of tabulating the proportions of the successful candidates who have selected each subject in the competitions for entrance into Woolwich and Sandhurst during the years 1880, 1881, 1882, 1883, very interesting information has been arrived at, which is given in a condensed form in the tables below.

Only the selections made by successful candidates have been considered, for on the whole they will show best which subjects have been most conducive to success. And as the marks allotted to the subjects are different in the two examinations, they afford a good criterion by which to judge in what way marks have during the last four years affected the selection of subjects. Compulsory subjects are not included. The percentages relating to Woolwich are calculated from data which include all the examinations in the years 1880, 1881, 1882, 1883. Those concerning Sandhurst are from data not quite so complete, but, as the larger tables from which these are taken exhibit considerable regularity, this is not of material importance.

		Mathematics	English	Latin	Greek	French	German	Experimental Scie	eogr. Geolc &c
SANDHURST	Marks allotted...	3000	3000	3000	2000	2000	2000	2000	2000
	Percentage of successful candidates taking the subject......	70	91	73	22	91	25	8	10
WOOLWICH	Marks allotted...	4000	2000	2000	2000	2000	2000	2000	
	Percentage of successful candidates taking the subject......	97	60				46		

The influence of the maximum marks allotted to the subjects is perceptible at a glance. The increased marks given for mathematics in the Woolwich competition raises the proportion of those who take up that subject from 70 per cent at Sandhurst to 97 per cent. at Woolwich. Similarly English and Latin are selected by 60 per cent. and 52 per cent. at Woolwich, where the maximum is 2000, against 91 per cent. and 73 per cent. at Sandhurst, where the maximum is 3000. And Greek, German, and Experimental Science are taking 29 per cent., 46 per cent., and 22 per cent. at Woolwich, where there is the same mark as for English and Latin, against 22 per cent., 25 per cent., and 8 per cent. at Sandhurst, where English and Latin have the higher mark of 3000, and the others only 2000. The positions of French is peculiar, but we observe the relatively better marks given in the Woolwich competitions has its effect, though there is less room for much increase. The selection of French by so large a proportion of the successful candidates both at Sandhurst and Woolwich, is probably largely due to the circumstance that it is taught in nearly all divisions of our schools, and that it is often begun earlier than Greek, German, and science, so that when candidates select the subjects they will study for these competitions, they already very often have made some progress in French and much less in the other subjects. Statistics, however, seem to show that French is more liberally marked than some of the others.

In the remaining subject, General and Physical Geography and Geology, there is a similar though smaller increase in the number of candidates taking it at Woolwich examinations, where its mark value is higher than at Sandhurst. This is just what the opinions of teachers have foretold. They say to do poorly in a subject counting 3000 will pay so much better than to do well in one counting only 1500, that in future nearly all candidates will take up the four subjects which are to count 3000; some who are very weak in one of these will take one of those marked 2000; and the rest of the subjects, including the science, they do not see their way to using at all. Accordingly, science teachers, even in those schools where science is most valued, are already hearing proposals to drop the regular science work hitherto done by boys who are looking forward to joining the army, and to substitute for it extra Latin. In other words, the new

regulations are already discouraging general education and encouraging an unfortunate system of specialisation.

II. The proportions of candidates who have chosen one of the branches of experimental science in these examinations show clearly that they are not generally regarded as paying subjects. At Sandhurst especially it is quite evident that there has been no considerable success in consequence of cramming in this subject. It has plainly not been worth while to cram it, nor to teach it for this examination, except in a few cases. At Woolwich under fairer conditions, it has been chosen by a greater number. Experience shows that in the Woolwich examinations candidates of real scientific ability who work well can do fairly, but only fairly, well, and accordingly such candidates are encouraged in those schools where science is taught to take up experimental science unless they are decidedly strong in some other subject. But the marks they get, even when successful, are not such as to encourage its adoption by any except those of a scientific ability quite above the average, and these do not want cramming. For example, a candidate standing second in order among the experimental science candidates lately obtained only 33 per cent. of the nominal maximum. And in one subject, chemistry, lads of such ability as would give them a fair chance of scholarships at our Universities had they time for sufficiently wide reading, will usually fail to get marks more than slightly exceeding 40 to 50 per cent. of the maximum, with the greatest diligence, even though their position on the list of experimental science candidates is a good one. These facts, and the absence of any rush on the subject seems quite inconsistent with the charge that experimental science has been a subject in which there has been much successful cramming—some there has no doubt been in this and in all subjects; candidates who have first-rate memories, and only moderate intelligence, will from time to time succeed by sheer industry in these and in all other competitions. Probably mathematics and experimental science suit these less than any other subject.

Geography, physical geography, and geology have been selected by rather more candidates both at the competitions for Sandhurst and Woolwich. From the nature of this subject it seems not impossible that there has been cramming in preparing for it. If so, the evil could surely be met, possibly by the changes proposed in Section III., combined with great care in setting the papers, and by the introduction of a *vivâ voce* examination.

III. As physiology is now extensively studied in the Universities, whence some of the Sandhurst candidates come, and is successfully taught in at least one great school—Eton—it is a question if the time has not come when it should be added to the science subjects examined.

And as practical physics is now taught in some schools, and examined at the scholarship competitions at Cambridge, it would be a gain if there could be a practical examination for candidates who take up physical subjects as there is for those who take up chemistry. This would act as a check on cramming, and would encourage students of a practical turn, and would encourage, as its absence discourages, this valuable branch of work in our public schools. One subject, chemistry, is encumbered by the addition of heat to it. Chemistry would be at least as difficult as the other divisions without this addition; with it, and its practical examination, it is in a most unfair position. It would probably be advantageous to add light to heat, and make them a new division. The scheme would then stand as follows:—

DIVISION *a*.—*Experimental Science*

1. Chemistry. With a practical examination.
2. Light and Heat. ,, ,, ,,
3. Electricity and Magnetism. ,, ,,

DIVISION *b*

1. Physiology. With some practical work.
2. Geography, Physical Geography, and Geology. With a *vivâ voce* examination on specimens.[1]

Candidates might be allowed to take one subject in Division *a* and one in Division *b*, which would be in accordance with the present plan at Woolwich, but would give greater choice of subjects. It would also be much fairer to one much-taught subject—chemistry.

IV. The very small proportion of the candidates for Sandhurst who select experimental science does suggest that in this case too high a standard is perhaps expected by the examiners, though it is probably a question of marks to a great extent. But with this exception, and if that very difficult subject, chemistry, were relieved of the addition of heat, on the whole it does not appear that the standard expected is much too high. It is true that there are other subjects marked more liberally; yet on the whole a high standard is more in the interests of science than a low one. The latter would encourage superficial teaching, and so lead to the discredit of the subject. Hitherto candidates of good scientific ability have been able to take advantage of their science at Woolwich if well taught, and if proper appliances for the work have been available. There does not seem therefore much ground for complaint on this score, though there has been a certain want of regularity in the marks awarded to similar boys in different subjects and at different examinations, which would probably be to a great extent removed if two papers instead of one were set on each subject, the papers being as far as possible of different characters. It has, however, been only just possible, even under the Woolwich system, for the scientific candidates to take up experimental science with the present standard of knowledge demanded, and a small difference in raising this standard or depressing the marks allotted to it would undoubtedly have very serious effects. The fairest method of allotting marks seems to be that adopted at Woolwich, where mathematics, which are essential, are marked above the rest, and the others are all upon an equal footing, free choice being allowed. To offer 3000 marks for four subjects, 2000 marks for two others, and 1500 for the rest, and to limit the candidates to four subjects, is equivalent to cutting out those for which 1500 are given, especially when it is a condition that of the four subjects selected three shall be taken from those for which 3000 marks are given, and only one at most from all the others. No doubt other plans which would be more satisfactory than that which has been employed at Woolwich could be suggested. But it is certain from past experience that a scheme of examination on the lines of the new regulations will seriously discourage the teaching of science in our public schools, and indeed will tend to narrow the instruction they give in all respects.

[1] Probably if the Geography were dropped and a higher standard of knowledge in the other two subjects were demanded, it would discourage superficiality, the Geography being retained in the preliminary examination, however, as a qualifying subject.

PROFESSOR TAIT'S "HEAT"

Heat. By P. G. Tait, M.A., Professor of Natural Philosophy in the University of Edinburgh. (London: Macmillan and Co., 1884.)

A TREATISE on heat by one so eminent, both as physicist and teacher of Physics, needs no apology, and yet no doubt the author is right in stating that his work is adapted to the lecture-room rather than to the study or the laboratory. Freshness and vigour of treatment are its characteristics, and the intelligent student who reads it conscientiously will rise from it not merely with a knowledge of heat but of a good many other things besides.

"If science," says our author (p. 368), "were all reduced to a matter of certainty, it could be embodied in one gigantic encyclopædia, and too many of its parts would then have . . . little more than the comparatively tranquil or, rather, languid interest which we feel in looking up in a good gazetteer such places as Bangkok, Ak-Hissar, or Tortuga." Not a few text-books of science are precisely of the nature of such a guide without its completeness, and while they carry the student successfully to the end of his journey, the way before him is made so utterly deficient in human interest that he reaches his goal with a sigh of relief, and looks back upon his journey with anything but satisfaction—as a task accomplished rather than as a holiday enjoyed. Now the presence of such a human interest is the great charm of the work before us. It may be a fancy on our part, but we cannot help likening our author to the well-known guide of Christiana and her family. Both have been equally successful in the slaughter of those giants whom the older generation of pilgrims had to find out for themselves and encounter alone. But here the likeness ends, for it is quite certain that those who place themselves under the scientific guidance of our author will not be treated like women or children, but they will be taught to fight like men. And surely to combat error is an essential part of the education of the true man of science, for, if not trained up as a good soldier of the truth to defend the king's highway, he will be only too apt to turn freebooter, and gain his livelihood by preying on the possessions of others.

The first chapter contains the fundamental principles. "Heat," says our author, "whatever it may be, is SOMETHING which can be transferred from one portion of matter to another; the consideration of temperatures is virtually that of the mere CONDITIONS which determine whether or not there shall be a transfer of heat, and in what direction the transfer is to take place."

Then follows a preliminary historical sketch of the subject, the result of which is that heat is now proved to be a form of energy. Again: "The mechanism upon which heat-energy depends is (probably at least) approximately known so far as regards heat in a gas and as regards radiant heat. Beyond these we have, as yet, little information on the subject."

The following is a digression by the way:—

"There can be no question about the fact that the *metre* is inconveniently long, and the *kilogramme* inconveniently massive, for the ordinary affairs of life. The average length of the arms of shop-girls, and the average quantity of tea or sugar wanted at a time by a small purchaser, have no conceivable necessary relation to the ten-millionth part of the quadrant of the earth's meridian passing through Paris, or the maximum density of water. But the standard *yard* and *pound* were, no doubt, originally devised to suit these very requirements as regards the average dimensions of the shop-girl or the paying powers of the ordinary customer. Yet this invaluable superiority of our *units* over those of the metrical system is, with an almost over-refinement of barbarism, thrown away at once when we come to multiples or submultiples."

It may be desirable to quote the author's own words regarding his classification of different kinds of heat:—

"In the first place, we have absolutely no proof that radiation from the sun is in any of the forms of energy which we call heat while it is passing through interplanetary space. That it is a form of energy, and that it depends upon some species of vibration of a medium, we have absolute proof. But it seems probable that we are no more entitled to call it heat than to call an electric current heat; for, though an electric current is a possible transformation of heat-energy, and can again be frittered down into heat, it is not usually looked upon as being itself heat. Just so the energy of vibrational radiation is a transformation of the heat of a hot body, and can again be frittered down into heat—but in the interval of its passage through space devoid of tangible matter, or even when passing (unabsorbed) through tangible matter, it is not necessarily *heat*."

That this is not a mere question of words may be seen from the following considerations. According to theory, all kinds of radiant heat, whether these have issued from a source of high or from one of low temperature, are in presence of an absolutely black surface at once and entirely converted into absorbed heat. On the other hand, absorbed heat is only entirely converted into radiant heat when the body from which it issues has been cooled down to the absolute zero of temperature, a condition which is practically unapproachable.

The following are the subjects which appear to us to be treated in the most original manner:—Thermo-electricity, combination and dissociation, conduction, convection, and radiation, discussion of isothermals and adiabatic lines. In the development of thermo-electricity and of conduction the author has taken a prominent part, and probably we must blame the late mild winter for our not hearing more about his latest research regarding the effect of pressure upon the point of the maximum density of water.

We cannot do justice to such a book in the course of a short notice like the present; we will therefore content ourselves with a few quotations and remarks. The following (p. 72) is an excellently clear definition of an isotropic body:—

"An isotropic body is one from which, if a small sphere were cut, it would be impossible to tell by any operation on it how it originally lay in the solid—it has, in fact, precisely the same properties in all directions."

In p. 91 an increase in clearness is produced by giving the coefficient of dilatation of mercury at various temperatures under three different heads, namely, mean coefficient of dilatation from 0°, coefficient referred to volume at 0°, true coefficient. The following statement will be found useful to meteorologists:—

"Vertical (convection) currents at definite places may be at once produced either by heating the requisite part of the lower portions of a fluid mass, or by cooling that of the upper portions. But the effects of cooling part of the lower portions, or heating some of the upper, are usually

much less important. Hence the grander phases of *ocean circulation* (except in so far as they depend on winds, and therefore on *atmospheric circulation*) are much more dependent upon polar cold than upon tropical heat. On the other hand, those of atmospheric circulation depend more upon tropical heat than on polar cold. For the great temperature effects are produced mainly at the upper surface of the ocean, and at the lower surface of the atmosphere. Hence, if there were no great modifying causes, we should expect to find (on the whole) the lower water, as well as the lower air, coming from both sides towards the equator, and the upper currents of each flowing to the poles."

Chapter XXI. is entitled "Elements of Thermodynamics." The subject is nevertheless treated in a very complete manner, and is evidently regarded by our author as something in the shape of a *header*. We gather this from the very characteristic invitation to take the leap which is addressed to the student in Art. 381. We shall not, however, repeat the invitation, but rather leave the reader to find it out for himself and then—take the leap.

Let us conclude with one more quotation :—

"We have merely to think of the ideas which we try to express by such words as Time, Space, and Matter, to see that, however far discovery may be pushed, our little 'clearing' can never form more than an infinitesimal fraction of the 'boundless prairie.' No part of this, however, can strictly be called inaccessible to unaided human reason, if time and patience fail not. But far beyond in one sense, though in another sense ever intimately present with us, are the higher mysteries of the true Metaphysic, of which our senses and our reason, unaided, are alike unable to gain us any information."

While cordially indorsing these views, the writer of this notice would remark how admirably fitted is such a science as Physics for the discipline of the human mind. It possesses that boundlessness which is the *ultimate* characteristic of all true knowledge, and this is so obvious that few are bold enough to represent our "little Physical clearing" as bounded by an "impenetrable wall" or by the "abyss."

The scientific incendiary (to change the metaphor somewhat) prefers to confine himself to regions where there is a large collection of inflammable materials, until at length his attempts are brought to an end by the copious stream of cold water with which the physicist is able to deluge the scene of his exploits.

BALFOUR STEWART

OUR BOOK SHELF

Beiträge zur Kenntniss der Liasischen Brachiopodenfauna von Südtyrol und Venetien. Von Hyppolyt Haas, Dr. Phil., Privat-docent an der Universität Kiel. Mit 4 lithographirten tafeln. 4to. (Kiel: Lipsius und Tischer, 1884.)

THIS is one of the numerous works which have been published during the last half century on the fossil forms of Brachiopoda, that most ancient, abundant, and anomalous class of the Invertebrata. Dr. Davidson has devoted the greater part of a tolerably long life to the study of this exceedingly interesting group; and the volume of the Palæontographical Society's publications for the present year will complete and close his valuable labours on the fossil Brachiopoda of Great Britain. He has kindly furnished me with the following critical notice of Dr. Haas's work, the title of which is above given :—

"Dr. Haas describes in his memoir some 40 species of Liassic Brachiopoda, and of which number 12 are new. In four admirably drawn quarto plates he gives figures of 32 species. The Liassic Brachiopoda from South Tyrol and Venetia are very remarkable, and have in part been described and beautifully illustrated by Gemmellaro, Böckh, Uhlig, Meneghini, Canavari, Oppel, Zittel, and Schmid; *Waldheimia perforata*, Piette, and *Spiriferina rostrata*, Schl., being the only species out of the number that occur in the Liassic rocks of Great Britain. Dr. Haas's work adds much to our knowledge with respect to the Liassic Brachiopoda, and his descriptions have been carefully drawn up. In 1881 and 1882 Dr. H. Haas and Dr. Camille Petri published a very important work, entitled 'Die Brachiopoden der Juraformation von Elsass-Lothringen,' accompanied by 18 beautifully drawn quarto plates. In this work the authors describe some 92 species from the Lias and Inferior Oolite, and of which a large proportion occur likewise in our British rocks. It is to be hoped that Dr. Haas will continue his valuable researches among the Brachiopoda."

'Non meus hic sermo!"

J. GWYN JEFFREYS

Tricycles of the Year 1884. By H. H. Griffin. (London: L. Upcott Gill, 1884.)

WHATEVER improvement in health and strength may have resulted from the now prevalent exercise of cycling, there seems to be a mental improvement, for a knowledge of the science of mechanics is more widely spread, or at any rate there is a more general desire to understand this science in so far as its application to the bicycle and tricycle is concerned. For this reason such a book as Mr. Griffin's "Tricycles of the Year" is likely to be of value, for in it he describes in simple language most of the tricycles which can now be obtained, giving particulars of dimensions and weight, and other information which a cyclist may require.

It is a pity that many well-known machines are not so much as mentioned, among which are the "Rudge," the "Cheylesmore," and the direct-action machines. Is it that there has been no improvement in any of these since last year? If so, why should the "Oarsman" be omitted or some others be described at length?

The good qualities and advantages of each machine are set forth plainly enough, while the defects are left to be discovered by riders. The author has no doubt acted wisely here; it would be next to impossible in dealing with such a multitude of often similar machines to make comparisons which cyclists who hold opposite opinions would not consider unfair.

The action of parts that are peculiar to any machine is carefully described, figures being inserted where necessary to make the text more comprehensible. The general appearance which many tricycles present is shown by a series of woodcuts.

Bicycles are not discussed, as they form the subject of a corresponding work.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.]

Chalk and the "Origin and Distribution of Deep-Sea Deposits"

I LOOKED forward with great interest to the conclusion of Messrs. Murray and Renard's "Origin and Distribution of Deep-Sea Deposits," hoping that some useful comparisons would

have been made between the present sea-beds and the Chalk, the Gault, and the Greensands, which appear to be among the deepest water deposits now accessible as dry land. Instead of this we are merely told that chalk "must be regarded as having been laid down rather along the border of a continent than in a true oceanic area" (NATURE, p. 134). All geologists are aware, since the publication of Dr. Gwyn Jeffreys' address to the British Association, and the appearance of Mr. Wallace's "Island Life," that some naturalists regard the Chalk as a shallow-water formation, but the former opinion, pronounced as it was by one of the most competent judges, was based exclusively on the present habits of the very few genera of Mollusca that have survived from the Chalk period, and seems quite in contradiction to the far more important groups, the Sponges, Echinodermata, and the minute organisms of which the formation is so largely composed, while no opinion has yet found its way into the hands of geologists regarding the depth of water indicated by the Crustacea and the fishes of the Chalk. Mr. Wallace's collation of the Chalk, as a formation, with the decomposed coral mud of Ooahu, is so fantastic as to have failed to carry conviction to the mind of any competent geologist. The points of resemblance between some Globigerina ooze and the Chalk are so numerous and peculiar, that surely the assertion that the latter is a littoral formation, while the former is oceanic, requires strong support. The relative analyses of chips from the Chalk and of Globigerina ooze, quoted by Mr. Wallace, are not by any means final or conclusive. We all know that the silica has been removed and segregated into flints from the White Chalk at Shoreham, and that the iron and other metals are also segregated into crystallised masses, so that a comparison of the Chalk, minus these, is misleading. In like manner the Grey Chalk at Folkestone has lost all its oxide of iron by segregation and crystallisation, and many of the layers are cherty, and unduly rich in silica obtained probably at the expense of other layers in which it is now relatively scarce. During the ages that Chalk has been elevated and has acted as a sponge for the collection of rain water, who can say what other of its constituents may not have been dissolved away or metamorphosed? Siliceous sponge skeletons have been replaced by calcite, calcite shells have been replaced by silica, whilst aragonite shells have been entirely dissolved away. In like manner, can it possibly be contended that the absence of volcanic matter in the Chalk is an important distinction between it and Atlantic ooze? It is an accidental lithological distinction, but nothing more, and merely shows that volcanic dust was not being ejected in the same masses as at present. The Cretaceous and Eocene eruptions, so far as I am aware, are all fissure eruptions of vast magnitude, and the contemporary rocks in their vicinity seem to show that they were not accompanied by the showers of ash that mark eruptions from craters at the present day. Messrs. Renard and Murray have had exceptional opportunities of studying this question, and have no doubt convincing proofs of their statement regarding the littoral character of the Chalk deposit; but I really think that, considering the national character of the undertaking which made the collection of proof possible, it should no longer be withheld. Geologists at present, supposing my feelings are generally shared, are asked to believe that an enormous formation, which shows little, if any, trace of the proximity of land, and abounds with the remains of deep-sea life, was laid down upon a coastline; but beyond the extravagant assertion that it is decomposed coral-mud no reasons whatever for this belief are brought forward, nor are any areas pointed out in which an equivalent to the Chalk is in course of deposition. I cannot conceive why our official geologists have ignored this, one of the most important questions in the whole range of the science. It is little to our national credit that, having spent vast sums in the collection of evidence, we are still in the dark as to its geological significance.

J. STARKIE GARDNER

A Rhyolitic Rock from Lake Tanganyika

THE interesting note by Dr. H. J. Johnston-Lavis on a volcanic rock from the shores of Lake Nyassa (NATURE, p. 62) calls to my mind a couple of specimens in my collection which, with not a few others of interest, have perforce remained for some time undescribed. They were given to me by N. F. Robarts, Esq., F.G.S., who received them from Capt. Hore of the London Missionary Society, by whom they were collected at Cameron's Bay on the south-west of Lake Tanganyika, a little north of the Lofu River. As they are evidently fragments of the same kind of rock, I have only had a slide prepared from one of them. The rock is externally of a pale yellowish- to reddish-gray colour; compact, but exhibiting faint traces of a fluidal structure, with occasional spots resembling small crystals of decomposed felspar. A fresh broken surface, however, shows the real colour to be a purplish brown, streaked and mottled with a pale reddish tint. Microscopic examination shows that the rock is a rhyolite, somewhat darkened with numerous specks of disseminated ferrite, with many clearer bands, indicative of a fluidal structure. In this matrix are scattered crystals of decomposed felspar, not exceeding ·1 inch in diameter, and a few plates of a ferruginous mica, also exhibiting signs of decomposition, with two or three granules of quartz. With crossed Nicols a minute devitrification structure is exhibited by the slide as a whole, and this is coarser and stronger in the clearer bands. Here crystalline quartz is developed, which assumes with the felspars on occasion a spherulitic or sometimes approximately micrographitic structure. The larger felspar crystals are rather decomposed, but orthoclase and a plagioclastic felspar can be recognised. Many distinct granules of iron peroxide (? hæmatite) are scattered about. Examination with high powers causes me to doubt whether the devitrification is complete in all parts of the slide, and whether the phenomena are not rather due to the development of a large number of minute crystallites of not very regular form in an isotropic base. In this, however, there is nothing exceptional.

From the structure I should consider it more probable that the specimen had been taken from a flow than from a dyke. I should suspect the devitrification structure to be the result of secondary change, and the rock not a very modern one. In some respects it reminds me of the pre-Cambrian rhyolites (devitrified) of Britain, but I should think it had not quite so high a percentage of silica, *i e.* that this did not exceed 70, and perhaps was rather less. Among the rhyolitic rocks which I described from Socotra (*Phil. Trans.* 1883, p. 273), collected by Prof. I. B. Balfour, were some of a rather dark purple colour, not unlike to this specimen from Lake Tanganyika.

T. G. BONNEY

Aseismatic Tables for Mitigating Earthquake Shocks

IN Mr. Topley's paper on the Colchester earthquake, which appeared in NATURE, vol. xxx. p. 60, he mentions the aseismatic joint designed by my father, Mr. David Stevenson, for mitigating the effects of shocks on lighthouses in countries subject to earthquakes, and from information which Mr. Topley has received and cites it would appear that the appliance had been tried in Japan, found wanting, and abandoned. The facts of the case, however, are as follows, and are supplied to me by Mr. Simpkins, who was engaged in fitting up the apparatus sent out from here, and has only recently returned from Japan. Of the seven lighthouse apparatus designed by Messrs. D. and T. Stevenson and furnished with the aseismatic joint and sent out to Japan, there are three at present in action, and have been so for ten years, viz. Mikomoto, Siwomisaki, and Yesaki. At Iwosima and Satanomisaki, in the south end of the island, the tables are screwed up so as not to act, as it is reported that no earthquakes are felt at these stations. At Tsuragisaki and Kashmosaki, which are revolving lights, the steadying screws sent out with the apparatus (to prevent the table oscillating while winding up the machine, which is the main inconvenience felt, and which was foreseen) were for some reason not put in at these stations, and the tables were firmly strutted with timber to prevent any motion. These two are the only lighthouses at which any damage has been done; while those stations at which the tables are in operation have never suffered at all, although they have been repeatedly subjected to shocks.

With regard to the effect of wind, to which Mr. Topley alludes, I may say that none of the *towers* are placed on tables, it is only the *apparatus* inside the lantern which is so treated, although my father proposed it for the towers themselves, and I have no doubt that, from the experiments I saw made here, they would have been equally effective. Two towers fitted with the tables were made and sent out to Japan, but were unfortunately lost at sea and not replaced.

The "Cotton-Spinner"

ON seeing my article on this rare British Holothurian, Mrs. Fisher—who, as Miss Arabella B. Buckley, is well known to a

large circle of readers—kindly sent me an account of her experience of the offensive use of the Cuvierian organs. She tells me that in the Bay of Rapallo at Santa Margherita, near Porto Fino, she dredged a large black Holothurian, and that "the tangled mass of white threads you mention is *so* sticky and in such quantity that, after having taken one of these animals out with my hand, I had considerable difficulty in freeing my fingers from the threads; indeed, my hand was not comfortable till I had washed it in hot water." On the other hand, an inquiry made of a gentleman living at Penzance, and interested in Echinoderms, resulted in the answer that he had never heard of the "Cotton-Spinner." F. JEFFREY BELL

The Red Glow

IN your issue of April 10 (p. 549) is the statement by an observer in Australia that the "*red glow* was margined by an *immense black bow* stretching across from north-west to south-east."

I wish to say that the above language almost exactly describes the appearance to which I alluded *on the same page* as "the *earth shadow* cutting off the upper rim of the first glow." The "black bow" of the Australian was evidently the shadow of the horizon projected on the haze stratum. In both the above cases the lower surface of the haze was evidently well defined, so that as the horizon intercepted the direct rays of the sun, a well-marked shadow moved westward and downward. Above this black rim or bow appeared the *secondary* glow, produced by the reflection of the sun's rays from that portion of the haze surface which was directly illuminated. Very often the second glow was more conspicuous and impressive than the first, because it shone against the dark sky of night.

In the *Proceedings* of some association I have just read an astonishing estimate of the height of the haze as 141 miles, based on the fact that it received the sun's rays one hour after sunset, the fact being strangely overlooked that the late reflection was a *secondary* one.

One evening the shadow or "black bow" was beautifully indented or serrated, doubtless by the shadows of remote cumuli such as are commonly seen in platoons on our evening horizons. The "black bow" was seen only during the first few days of the glows in September. S. E. BISHOP

Hawaiian Government Survey, Honolulu, May 20

P.S.—I hoped long ere this to have sent you data from the Caroline Islands received per *Morning Star*, now much overdue. We fear she has suffered disaster.

Light Phenomenon

THIS evening towards sunset, at 7.55 p.m., there was a column of light extending from the upper part of the setting sun to about 20°, the column being truncated and perpendicular to the horizon. After remaining thus for about two minutes, the sides of the pillar lost somewhat of their perpendicularity, and, with the whole volume of the sun, put on prismatic colouring, the ray (a single one, and still truncated) at times appearing to be a wave of flame. I observed this, with four or five other persons, from the cliffs, and should like to know if the peculiarity of this sunset was observed by others. It continued until 8.20 p.m., when the sun was below the horizon, and the wave of flame ceased. I can hardly better describe this ray than as being very like a northern light, only extremely circumscribed in size, and intensely brilliant. R. D. GIBNEY

Falmouth, June 21

Atmospheric Dust

IN connection with the recent experiments of Dr. Lodge and Mr. John Aitken (described in late numbers of NATURE) on the filtration of dusty atmospheres, I have ventured to call your attention to the following, as of possible interest. I have had frequent occasion to note the intensity of the so-called "rain-band," an absorption-band of terrestrial origin, due probably to the dust and water-vapour present in the atmosphere, and of just less refrangibility than the less refrangible of the D lines, and have at present two continuous records of observations taken, in the main, five times a day, running back a year and a half or so. I have also a very thorough list of the auroral displays which have occurred for the same period in this vicinity. Granting that the aurora is an electric discharge in high regions of the atmosphere, or, more accurately, where its density is inappreciable compared with that at the earth's surface, and knowing that according to these recent experiments an electric discharge is capable of precipitating the dust-particles in the atmosphere, it should follow that at times of auroral display, or immediately following, the intensity of this rain-band should be at a minimum. Searching the records to ascertain if any such correspondence could be noticed, it is quite astonishing to find how distinct and well marked this variation in the intensity of the rain-band at times of auroral occurrence is. The atmosphere is full of fine dust-particles, and our very general, though not yet decisively proven, belief is that the aurora is somewhat of a glow-like discharge from electrified air strata, in whose vicinity the density of the dielectric is inconsiderable. The direct inference is that at such times the fine dust and vapour particles are deposited, made to settle, or, uniting together, form an agglomeration, and become perhaps cloud-nuclei. Perhaps other evidence on this matter can be elicited. The records at hand show very plainly just such an agreement as was anticipated.

Some Botanical Queries

THERE is a plant here with a very large bulb, *Scilla maritima* (?), whose flower I have not seen. I grew two of them in pots last year, but they failed. This plant is set by the peasants near the fig-trees with the idea that these latter will produce better fruit. Is this a mere superstition? or can the Scilla be connected in any way with caprification?

Is *Lilium bulbiferum* known to be polygamous? The greater part of the specimens I have found in the mountains near here are staminate, but in some there is a very minute though perfectly formed pistil. Müller, my only book of reference, says nothing on this point.

Is *Trifolium repens* among the list of cleistogamous plants? I am watching a specimen which seems to produce abundant fruit, but no ordinary flowers. LIGUS

Nice, France, June 20

Primæval Man and Working-Men Students

UNDER the above heading you published a letter from me in NATURE, August 2, 1883, p. 320, giving the names of four thoughtful artisans, who, after studying the Pitt-Rivers collection of antiquities, and reading my notes in NATURE, had made finds of Palæolithic implements in Essex. Ten months have passed since that letter was published, and a fifth student, Mr. W. Swain, has now joined the original party of four. On Sunday, June 15, these admirable workers called upon me with their recent discoveries. They consisted of fifteen Palæolithic implements found in the drift gravels of Leyton, Wanstead, and Plaistow, with the usual complement of flakes. Some of the implements were of the older abraded class, others were as keen as knives, and from my "Palæolithic Floor," traces of which, as I have pointed out, may be seen in Essex. Three nondescript tools were also lighted on, and four hammer-stones of quartzite with abraded ends, one from Nazing; five Neolithic instruments from Jordan's Wood, and a large collection of flakes.

The excursions for these tools and flakes have necessarily all been made on Sundays. The finders of the stones are not mere collectors, but men who have mastered the meaning of their subject. W. G. S.

FORESTRY

THE approaching International Forestry Exhibition at Edinburgh, which is to open on July 1 next, and which promises to be a very successful affair so far as the variety of the exhibits and the general arrangements of the Exhibition are concerned, will, it is hoped, prove something more than a mere show during the months it is open to the public. Though the objects exhibited will, in all probability, be a source of considerable attraction and instruction, inasmuch as the arrangement and scope of the several classes seem to have been carefully considered, it is much to be hoped that the Exhibition will be

the means of leaving a lasting improvement on the condition of forestry in this country. One thing it certainly must do, and that is it will draw attention to the great importance of practical forestry in utilising and developing the resources of forest produce, and in directing attention to these products the eyes of many will be opened as to their value, whether to the consumer or to the producer. There is, however, a higher aim in the prosecution of scientific forestry than even these points just referred to, namely, the preservation of indigenous arboreal vegetation and the securing of a sufficient rainfall.

The superiority of our Indian Empire and many of the British colonies, as well as France and other countries of continental Europe, over Great Britain itself must, from the nature of things, be prominently seen in the forthcoming Exhibition, whether in the character of the exhibits themselves, or in the exemplification of forest workings. This, then, should bring some good results towards putting our own country on a more satisfactory footing regarding the teaching of the principles of forestry, so that we may not in the future stand in the unenviable position of being about the only country of any importance which has not its School of Forestry or some institution or college where the Government recognises the importance of the subject by a grant from the Imperial Exchequer. The position of England in this respect as compared with other countries was admirably shown by Col. Pearson in his paper on "The Teaching of Forestry," read before the Society of Arts on March 1, 1882. He then pointed out that, "besides the establishments for teaching forest management in Germany and France, schools of sylviculture now exist in all the principal countries of Europe except in Great Britain. Austria, Italy, Russia, Switzerland, and even Roumania, most of them, after sending pupils for a few years to the French and German schools, have set up schools of their own, and thus rendered themselves independent of foreign educational aid." After referring to the fact that America was at that time about founding a similar school, Col. Pearson says:—

"It is to be regretted that as yet no steps have been taken to do the same in Great Britain, for with us, as elsewhere, a forest school would become not only an establishment for teaching sylvicuture, but also a centre of study and practical observation from whence a knowledge of sylviculture as a science would be spread abroad for the benefit of society in general.

"It is certain that, unless the forests of a country are properly and economically managed, the time may come when, as was the case in India, it will find itself without the means of procuring the needful supply of timber, except at an extravagant price; while at the same time the general interests of the community require that a fairly abundant and cheap supply should be constantly available. This is especially the case where, as in the great continental areas, deficiency in the means of transport, or the distance from the timber-producing tracts, adds materially to its cost. In such cases experience has shown that the only practicable way out of the difficulty is for the State to intervene; and although in England we have special facilities for supplying our wants from abroad, owing to our extended commerce with all countries, the extreme limits of a reasonably cheap supply seem to have been reached; and at all events State action seems so far desirable as to help private proprietors to make the best use of their timber-producing lands."

Following on this, namely, in August last, Sir John Lubbock asked from his place in the House of Commons whether Her Majesty's Government, during the autumn then ensuing, would consider the question of forest education in this country, and whether the national forests might not be utilised for this purpose, taking occasion to point out that our woods and plantations amounted in round numbers to 2,500,000 acres, and, moreover, that in Scotland and Wales it was calculated that there were 5,000,000 or 6,000,000 acres at present almost valueless, which, if judiciously planted, would give large results, thereby showing that the subject was one of vast importance. Sir John Lubbock further said:—"We were the only important nation in Europe without a forest school, and yet if we included our colonies, our forests were the largest and most valuable in the world. It appeared to be a very strong argument in favour of the establishment of a forest school in this country that at present the young men who were going out to manage our Indian forests had to be sent for instruction to the great French Forest School at Nancy. No doubt that this was a most excellent institution, and we were indebted to the French Government for the courtesy with which they had received our English students; but the system of education given there naturally contained some branches—as, for instance, the study of French law—that were not adapted to English students, while there were many other considerations, such as climate, which rendered a Continental school less suitable for English requirements. He might add that no young Englishman as a matter of fact, went there excepting those intended for the Indian service. For our colonies, again, the establishment of a good forest school here would be of very great importance. A judicious management of their woods would add considerably to their income." As an illustration of the need of some system of forest teaching in this country, Sir John Lubbock referred to the recent appointment of a Forest Commissioner by the Government of the Cape of Good Hope at a high salary, a French gentleman having been selected in consequence of the failure to find a properly qualified Englishman.

India was perhaps the first country belonging to the British Empire to organise a complete system of forest conservancy, and this was not effected before it was absolutely needed, for many of the valuable timber trees of India were threatened with annihilation in consequence of the reckless manner in which they were felled to supply the wants of the people. The appointment of Dr. Brandis as Inspector-General of Forests, in 1863, was the commencement of a better state of things, "and in 1867 his scheme for training foresters for India in the schools of France and Germany was, after much discussion, adopted finally by both the Home and Indian Governments." The outcome of this is well known, and India now has a large and well-trained staff of educated forest officers, who not only furnish valuable and interesting periodical reports on the forests of their respective districts, but standard works on the subject of India's arboreal vegetation are not amongst the least important result of their labours. As a proof of this we need only mention the titles of Beddome's "Flora Sylvatica of Madras," published in 1873; Brandis's "Forest Flora of North-West and Central India," published in 1874; Kurz's "Forest Flora of British Burma," published in 1877, and last, though not by any means least, Gamble's "Manual of Indian Timbers," published in 1881.

Trained as Indian forest officers now are before commencing their duties, and with the books we have mentioned as their guides, it is not difficult to understand that our Indian Empire possesses a well-organised Forest Department, and many of the colonies are following, if not on exactly similar lines, the example set for the preservation of their forests. With all these indications around us that foreign countries and our own dependencies are fully alive to the importance of a proper management of their forests, it is not a little remarkable that we in this country are no farther advanced in the matter of establishing forest teaching here than we were two years since, when the subject was so strongly represented by Col. Pearson, or when nearly a year since Sir John Lubbock revived it, and placed the matter prominently before the

present Government. It is therefore sincerely to be hoped that the forthcoming Exhibition at Edinburgh will be the means of putting a new spoke in the wheel, and that before the close of the Exhibition, or soon after, something tangible may have resulted in making forestry one of the branches of education either in distinctly constituted forest schools, or in our present agricultural colleges.

It is satisfactory to know that the arrangements of the Exhibition are in a forward state, and that, if the promises which have been received by the executive are fulfilled, the Exhibition will exceed the anticipations of the promoters. JOHN R. JACKSON

RAINFALL OF NEW SOUTH WALES[1]

UNDER the energetic direction of Mr. Russell the investigation of the rainfall of New South Wales is being prosecuted with much success, and the interest of the colonists may now fairly be regarded as awakened to the importance of the inquiry. This is evidenced by the recent rapid increase of stations, the number of rain stations for the five years ending 1882 being 96, 153, 191, 256, and 308, having thus trebled during this brief interval. A comparison of the maps of stations for 1878 and 1882 shows that the increase has been pretty evenly distributed over the whole colony; and of particular importance is it to note the spread of the rain-gauge over the extensive regions which lie to the north and north-west of the Murray River.

Mr. Russell draws pointed attention, in the following extract, to the practical value to the colonists of well kept rain registers:—

"As a proof of the necessity for the use of the rain-gauge all over the colony, not only for purposes of science, but also as a necessary instrument on every run, I may mention that on Goolhi station six gauges are kept on various parts of the run, and the records range from 19·81 inches to 27·75 inches. It would obviously lead to a false estimate of the grass the run would produce if only one gauge had been used, and that one where only 19·81 inches were recorded. I hope that the facts which the yearly records bring to light will have the effect of awakening those interested to the immense importance of collecting these statistics carefully and at once, so that every year will add to the knowledge which will be of such value in forming estimates of the seasons which are to come, and of the possibility of conserving water."

Lately much speculation was indulged in, and various schemes were proposed of increasing by artificial means the rainfall of New South Wales, particularly in seasons of drought when day after day the sky becomes covered with dark, dense-looking clouds which regularly pass away without a drop of rain. In these cases, science can as yet hold out no hopes to the agriculturist. The successful instances of rain-production by artificial means have occurred when the atmosphere in the district where the experiment was made was at or near the point of saturation, a state of things which does not exist in the arid plains of the interior of Australia under the meteorological conditions when clouds daily darken the skies and as regularly mock the expectation of the farmer.

It must then be to a judicious and skilful cropping of the rainfall that the Australian farmer must look for the supply of his wants in the dry season and still more in seasons of exceptional drought. Now, as contributions towards the solution of this problem, the annual rainfall reports of Mr. Russell are simply invaluable. These reports give the rainfall and total days of rain for each month and for the year, to which is added the mean annual rainfall and rainy days calculated from previous years' observations at each place available for the purpose. The annual rainfall for each year is represented on a large map of the colony, 22 by 26 inches, where the fall for each station is entered in its place as a black spot, the diameter of which is proportioned to the quantity of rain. By this device, the eye takes in readily and at a glance the distribution of the rainfall for the year. The comparative results of the five years for the different districts of the colony are most instructive.

Owing to its position on the globe and its physical configuration, New South Wales presents extremely different climates according to the varying amounts of the rainfall. Thus at Antony, on the coast near the borders of Queensland, the mean annual rainfall amounts to 65·15 inches; whereas at Mount Poole, in the extreme north-west, it is only 8·38 inches. For the nine years beginning with 1874, an approximation to the annual rainfall of the colony for each year has been calculated by Mr. Russell, the results for the separate years being 33·46, 29·38, 27·66, 20·48, 25·05, 30·75, 19·93, 20·73, and 20·11 inches, each of the last three years showing a marked deficiency. Now the interesting point is this, and it is a peculiarity which every other country possesses, but particularly those which exhibit climates so diversified as New South Wales, viz. that the rainfall of any month, or of any year, is very far from being equably distributed. The amounts of the excesses above, or the defects from, the average, tend really to partition the country into several well-defined rain districts for the time, these being determined apparently by river basins, watersheds, and other features of its physical configuration taken in connection with their relations to the thunderstorms and the rain-bringing winds. It is quite in the future, as an outcome of Mr. Russell's work, that the settlers in different parts of the colony will receive specific directions as to the cropping of their rainfall so as to provide even against the recurring calamitous droughts of the Australian climates.

An interesting feature of the reports are the diagrams, showing, by curves, the heights for each day of the Darling, Murrumbidgee, and Murray Rivers. A heavy flood occurred at Bourke, on the Darling River, on February 4, 1882, and reached its maximum, 26 feet 2 inches, by the end of the month, and the river did not fall to its summer level until April 5. This flood was occasioned by heavy tropical rains, from February 1 to 7, that fell over the northern part of the Darling watershed, which took two months to drain off, as is proved by the fact that little or no rain fell during the latter half of February and all March. In a few years these systematic observations of the heights of the principal rivers of Australia will furnish invaluable data for the determination of not a few important problems of meteorology and physical geography, which the marked insular character of this continent is so well suited to elucidate.

[1] "Results of Rain and River Observations made in New South Wales during 1878-82." By H. C. Russell, B.A., Government Astronomer for New South Wales.

CALCUTTA BOTANIC GARDEN

SIR JOSEPH HOOKER has kindly placed at our disposal the following letter on the Calcutta Botanic Garden:—

"Our beautiful garden is now looking very nice. Let me tell you what I am looking out upon. On the right is a fine *Terminalia Catappa*, a mass of dark green foliage from base to summit, its branches with a quantity of *Soranthus longiflorus* on them. Further off, towering in the distance, is a clean-stemmed, stately-looking *Dipterocarpus alatus*, its branches the roost of vultures and *cheels*. Almost as tall, to one side of the Dipterocarp, is a beautiful *Terminalia Arunja*, with mahoganies and the golden-flowered *Peltophorum* in front. *Dillenia pentagyna* in front, and *Morinda tinctoria* covered with masses of *Vanda Roxburghii*. There is a fine *Adina cordifolia*, one of the monarchs of the garden; its straight, stout stem, disdaining to bend in the sudden squalls and rain-storms, bears evidence of having been topped before,

and I am always expecting to see it go. At its feet cluster our bed of Cycads, the latter shaded by young Oreodoxas and Caryotas, and with the margin of the bed fringed by the long feathered leaves, plume-like, of *Phœnix rupicola*. Here and there gleams of silver catch the eye, as the sun, striking on the ornamental stretches of water, glances through the foliage. To the left another member of that beautiful section of the *Rubiaceæ*—the *Nauclea*—occupies a prominent place, its stem the home of the handsome blossoms of *Vanda teres*. The pretty marble pillar and urn to the memory of Col. Kyd is seen through the branches. From it roads lead to the principal landing-stage bordered by Oreodoxas, mahoganies, and our only attempt at ribbon gardening, long lines of Acalyphas, &c. Another road, straight for nearly, if not quite, half a mile to one of the exits, has an avenue of *Polyalthia longifolia*, sacred to the Hindoos, and groups of Betle palms; then of Oreodoxas, and lastly of *Inga Saman*. We have great difficulty with the Oreodoxas on account of a beetle that lays its eggs in the terminal buds. Still another road leads to the Orchid House bordered by clumps of graceful bamboos. In the house we generally manage to have a pretty show, and its neighbourhood in the proper season is gay with the blossoms of *Amherstia Gustavia*, *Thunbergia Napoleona*, &c. *Magnolia grandiflora* is flowering with us just now. What a glorious flower it is! Yesterday and the day before there came down on us one of the sudden miniature cyclones that we are so liable to have at the approach of the change of the monsoon. It blew, rained, and hailed tremendously. The trees tossed their arms and wailed, poor things, with such effect that their branches everywhere broke and strewed the ground. However only one small mahogany fell. It was quite cold, and the rain froze, as it was falling, into lumps as big as marbles."

THE EXTINCT LAKES OF THE GREAT BASIN

THE Great Basin of North America presents the most singular contrasts of scenery to the regions that surround it. East of it rise the dark pine-covered heights of the Rocky Mountain system, with the high, bare, grassy prairies beyond them. To the west tower the more serrated scarps of the Sierra Nevada, with the steep Pacific slope on the other side. The traveller who enters the Basin, and passes beyond the marginal tracts where, with the aid of water from the neighbouring mountains, human industry has made the desert to blossom as the rose, soon finds himself in an arid climate and an almost lifeless desert. The rains that fall on the encircling mountains feed some streams that pour their waters into the Basin, but out of it no stream emerges. All the water is evaporated; and it would seem that at present even more is evaporated than is received, and that consequently the various lakes are diminishing. The Great Salt Lake is conspicuously less than it was a few years ago. Even within the short time that this remarkable region has been known, distinct oscillations in the level of the lake have been recorded. There are evidently cycles of greater and less precipitation, and consequently of higher and lower levels in the lakes of the Basin, though we are not yet in possession of sufficient data to estimate the extent and recurrence of these fluctuations.

It is now well known that oscillations of the most gigantic kind have taken place during past time in the level and condition of the waters of the Great Basin. The terraces of the Great Salt Lake afford striking evidence that this vast sheet of water was once somewhere about 1000 feet higher in level, and had then an outflow by a northern pass into the lava deserts through which the cañons of the Snake River and its tributaries wind their way towards the Pacific. Mr. Clarence King, Mr. Gilbert, and their associates in the Survey of the 40th Parallel, threw a flood of light upon the early history of the lake and the climatic changes of which its deposits have preserved a record. They showed that the present Great Salt Lake is only one of several shrunken sheets of water, the former areas of which can still be accurately traced by the terraces they have left along their ancient margins. To one of the largest of these vanished lakes the name of the French explorer Lahontan has been given. The geologists of the 40th Parallel Survey were able to portray its outlines on a map, and to offer material for a comparison between it and the former still larger reservoir of which the present Great Salt Lake is only a relic. The United States Geological Survey has since begun the more detailed investigation of the region, so that ere long we shall be in possession of data for a better solution of some of the many problems which the phenomena of the Great Basin present. In the meantime Mr. J. C. Russell, who has been intrusted with this work, has written an interesting and suggestive preliminary report of his labours.

The average rainfall of the area of the Great Basin is probably not more than 12 or 15 inches. In the more desert tracts it may not exceed 4 inches, though in the valleys on the borders of the Basin it may rise to 20 or 30 inches. The rain falls chiefly in autumn and winter, consequently many of the streams only flow during the rainy season, and for most of the year present dry channels. Even of the perennial water-courses, the larger part of their discharge is crowded into a brief space towards the end of the rainy season. Most of the streams diminish in volume as they descend into the valleys, and many of them disappear altogether as they wander across the blazing thirsty desert. Loaded with sediment, and more or less bitter with saline and alkaline solutions, they do little to redeem the lifelessness of these wastes.

Over the lower parts of the surface of the Basin are scattered numerous sheets of water. Where these have an outflow to lower levels they are fresh, as in the examples of Bear Lake, Utah Lake, and Tahoe Lake. But the great majority have no outflow. Some of them are merely temporary sheets of shallow water, appearing after a stormy night, and vanishing again beneath the next noonday sun, or gathering during the rainy season, and disappearing in summer. Yet in some cases these transient lakes cover an area of 100 square miles or more. When they dry up, they leave behind them hard smooth plains of grayish mud, that crack up under the burning sun, and then look like a broken mosaic of marble. Of the permanent lakes the largest is the Great Salt Lake. It is also by much the most saline. Though all of them are more or less charged with alkaline and saline solutions, the percentage of these impurities is in some cases not so great as to prevent the water from being drunk by animals, or even on an emergency by man himself. Nothing in the physics of the Basin is more remarkable than the great diversity in the amount and nature of the mineral substances in solution in the lakes.

The vanished sheet of water, or "fossil lake," as the American surveyors call it, known as Lake Lahontan, lay chiefly in the north-west part of Nevada, but extended also into California. In outline it was exceptionally irregular, being composed of a number of almost detached strips and basins connected by narrow straits, and sometimes separated only by narrow ridges. It inclosed a rugged mountainous island 126 miles long from north to south, and 50 miles broad, which contained two lakes, neither of them apparently overflowing into the main lake. The Central Pacific Railroad passes for 165 miles through the dried-up bed of Lake Lahontan. From the windows of the car one can look out upon the ancient clay floor of the lake and mark the marginal terraces winding with almost artificial precision along the bases of the hills. The larger basins, which were formerly united into one continuous sheet of water, still hold lakes, all of which are more or less saline and alkaline, but they are far from being such concentrated brines as might be

expected were they due to the progressive evaporation of the large original lake.

In tracing back the history of this interesting topography, we are first brought face to face with the fact that the area of the Great Basin has within recent geological times been subject to powerful and long-continued subterranean movements. In numerous cases, rocks have been fractured and displaced to an extent of 4000 or 5000 feet. So recent are some of the fractures that they actually cut through the alluvial cones that stream out from the base of the mountains, and in numerous instances displace the terraces of the old lake to the extent of 50 or 60, or sometimes even 100 feet. There seems no reason to dispute the conclusion to which Mr. Russell and his colleagues have come, that the movements are actually still in progress, and that the constant occurrence of hot springs along the lines of recent fracture may be taken as evidence of the conversion of the subterranean movement into heat.

What may have been the topography of the region before the first depression and isolation of the Great Basin is still unknown. Doubtless the ground had undergone extensive denudation as well as great subterranean disturbance. Considerable irregularities of surface would also necessarily be produced by the intermittent discharge of volcanic rocks. When this uneven floor sank below the level of the surrounding tracts so as to become a basin of inland drainage, a magnificent series of lakes was established. Of these the largest, to which the name of Lake Bonneville has been given, and of which the Great Salt Lake is the diminished representative, covered an area of not less than 19,750 square miles. Lake Lahontan was of hardly inferior dimensions, these two hydrographic basins occupying the whole breadth of the Great Basin in the latitude of the 41st parallel. No fewer than fifteen other smaller basins have been discovered, which, though now either dry or partially covered with saline or alkaline waters, were well-filled lakes at a former period.

It is some years since Mr. Gilbert, from a study of the deposits left by Lake Bonneville, announced his conclusion that they bear testimony to a remarkable oscillation of climate between humidity and aridity. Similar deductions have now been drawn from the deposits of Lake Lahontan. Previous to the appearance of this body of water the climate is believed to have been at least as dry as it is at present, when alluvial cones were pushed outwards from the base of mountains into the area of the future lake. Then came a moist period, when the hollow of Lahontan was filled up with water to a depth of 500 feet above its present desiccated floor in the Carson Desert. At or about this height the water must have stood a long time, for it has deposited, along its rocky margin and round its islets, a thick mass of calcareous tufa. That the water, if not fresh, was at least not so saline as to be inimical to life, is shown by the abundant occurrence in it of fresh-water gasteropods. An epoch of aridity ensuing, the lake fell to so low a level as to become intensely bitter and alkaline, depositing thickly along its margin crystals, six or eight inches long, of gaylussite (a hydrated carbonate of soda and lime). The soda of these crystals having been subsequently removed, the deposit is one of tufa, mainly composed of calcareous pseudomorphs after gaylussite. Next followed a period of increased precipitation, when the lake rose to within 200 feet of its highest level, and when the thickest and most abundant of the tufa deposits of the region was laid down to a depth of sometimes 20 or even 50 feet. This third incrustation of tufa was formed mainly along the rocky shores and islands; but curious mushroom-like protuberances of it likewise gathered upon stones lying on the floor of the lake. The water then rose to the highest level it ever reached, since which time the climate has again become arid. From the fact that the isolated lakes of the Lahontan Basin are not the saturated alkaline and saline solutions which they would certainly have been had they resulted from the evaporation of such a sheet of water as that in which the three tufa terraces were elaborated, it is inferred that the whole of the original lake was evaporated to dryness, and that its alkalies and salts, having been precipitated at the bottom, were covered over with a layer of mud so as to be partially protected from rapid solution. The existing lakes may thus be supposed to be the result of a subsequent diminution of the extreme aridity, but the time within which they have been in existence has not been long enough to enable them to become as bitter and saline as the original lake.

Such are some of the views which renewed exploration of this weird region has suggested to the able surveyors who have undertaken its investigation. Mr. Russell's report, lucid and interesting as it is, must be regarded as merely a prelude to the fuller results which he and his colleagues are gathering for the good of science, and to the credit of the admirably organised and administered Geological Survey of the United States.

NOTES

PROF. FLOWER, F.R.S., will preside at a meeting which it is proposed to hold on Tuesday next, July 1, in the lecture-room of the Natural History Museum, when Mr. R. Bowdler Sharpe will read a paper on the expediency or otherwise of adopting trinomial nomenclature in zoology. Many British naturalists have been anxious to meet the distinguished American naturalist, Dr. Elliott Coues, who is now on a visit to this country, and to exchange views with him on the subject of nomenclature. Invitations have been sent to a large number of the leading British zoologists, and an interesting discussion is expected.

THE Prince of Wales, President of the City and Guilds of London Institute, opened the Central Institution, Exhibition Road, yesterday afternoon at four o'clock. The Education Section of the International Health Exhibition, in the south wing of the Central Institution, was opened at the same time.

THE following additional donations to the Equipment Fund of the Central Institution of the City and Guilds of London Institute have been voted in response to the appeal of the Prince of Wales:—The Goldsmiths' Company, 4000*l.* (subject to confirmation); the Salters' Company, 525*l.*; the Cordwainers, 250*l.* The Plaisterers have increased their annual subscription from 50 guineas to 100*l.*

IT is stated that the English Foreign Office is endeavouring to obtain the co-operation of the German Government in the International Educational Conference to be held at the South Kensington Health Exhibition about the middle of August. The Committee attaches special importance to the attendance of representative German pedagogues (this word being used in the higher and German sense) at this conference to read or communicate papers especially on the subjects of technical and secondary education and the organisation of universities; and it is particularly anxious to know, as early as possible, the names of any Germans of note who may be disposed to attend, and the subjects likely to be selected for papers.

A LARGE and influential deputation, including the Earl of Rosebery, the Earl of Fife, Mr. Stephen Williamson, M.P., Hon. R. P. Bruce, M.P., Prof. Cossar Ewart, Prof. Macintosh (St. Andrew's), a number of Scotch M.P.'s, and other gentlemen, waited last Monday on the Home Secretary with the view of impressing on the Government the importance of granting further funds to the Scottish Fishery Board to further scientific investigation into the habits of herring and other food fishes. The principal lines of proposed inquiry are: (1) The examination of the spawning beds around the Scottish coast with the

view of increasing the fishing, more especially on the west coast; (2) the further collection of material for determining the nature of the food of the useful fishes met with on the Scottish coast; (3) the further investigation of the percentage of immature herring and other food fishes destroyed under present methods of fishing; (4) the investigation of the influence of sea-birds, parasites, &c., on the supply of food fishes; (5) the study of the development, rate of growth, and general life history of the herring and other economic fishes, and the further study of the spawning process, and the nature of the eggs of fish; (6) the determination of the best means of restocking deserted fishing grounds, by artificial cultivation or otherwise, of herring, cod, flat fish, &c.; (7) the determination of the practicability of increasing the supply by artificial means of lobsters, mussels, oysters, and other shell fish; (8) the inquiry as to the influence of fungi and other minute organisms in destroying the life of useful fishes, and the conditions which predispose to the attacks of these organisms. The Board estimates that a sum of at the very least 1000*l*. will be required during 1884-85 in order to carry on such inquiries properly. It would also immensely facilitate matters if the sailing cruiser belonging to the Board were superseded by a steam-vessel of somewhat larger size, and H.M.S. *Jackal* replaced by a seaworthy boat adapted for the work of a fishery cruiser. It is also of importance that the Admiralty should encourage and take part in scientific researches, not only on our own coasts but all over the world. Comparatively little has been done by Great Britain for the furtherance of our knowledge of the nature and habits of fish on her coast, important as these are as articles of food and commerce. The Board confidently anticipates that with the assistance now asked the investigations would yield most excellent results, as the Board is already an institution with a large staff of intelligent officers capable of making observations, collecting materials, &c., as several distinguished naturalists and the scientific members have promised to assist it gratuitously, and, moreover, that the exertions already made have yielded results of the highest promise. The deputation was most favourably received.

THERE has been considerable alarm recently with reference to the parasites in that useful and plentiful fish, mackerel; so much so that Prof. Huxley has thought it advisable to write a letter to Mr. J. L. Sayer of Lower Thames Street, showing that any such alarm is unnecessary:—"It is perfectly true," he writes, "that mackerel, like all other fish, are more or less infested by parasites, one of which, a small thread-worm, is often so abundant as to be conspicuous when the fish is opened. But it is not true that there is any reason to believe that this thread-worm would be injurious to a man, even if he swallowed it uncooked and alive, and to speak of it as a possible cause of cholera is sheer nonsense. I have no doubt that the 'excessive use of mackerel and mild ale,' whether separately or in combination, would be followed by unpleasant results, not only at this season of the year but at any other. But I undertake to say that the consequences would be the same whether the fish contained thread-worms or not. It is very much to be regretted that the food-supply of the people should be diminished, and that the fishing population should be robbed of the fruit of their labours by the authoritative propagation of statements which are devoid of foundation; and if you think the publication of this letter will be of any use to the public and to the fishing interest, it is at your service."

A *conversazione* will be held at the International Health Exhibition by the Council of the Society of Arts, in conjunction with the Executive Council of the Exhibition, on Wednesday, July 9. The whole of the buildings will be open, and the gardens will be illuminated.

THE Council of the Society of Arts have awarded the Society's Silver Medals to the following readers of papers during the Session 1883-84:—The Most Hon. the Marquis of Lorne, K.T., for his paper on "Canada and its Products"; Rev. J. A. Rivington, for his paper on a "New Process of Permanent Mural Painting, invented by Joseph Keim"; C. V. Boys, for his paper on "Bicycles and Tricycles"; Prof. Fleeming Jenkin, F.R.S., for his paper on "Telpherage"; I. Probert, for his paper on "Primary Batteries for Electric Lighting"; H. H. Johnston, for his paper on "The Portuguese Colonies of West Africa"; Prof. Silvanus P. Thompson, for his paper on "Recent Progress in Dynamo-Electric Machinery"; Edward C. Stanford, F.C.S., for his paper on "Economic Applications of Seaweed"; W. Seton-Karr, for his paper on "The New Bengal Rent Bill"; C. Purdon Clarke, C.I.E., for his paper on "Street Architecture in India." Thanks were voted to the following Members of Council for the papers read by them:—W. H. Preece, F.R.S., vice-president of the Society, for his paper on "The Progress of Electric Lighting"; B. W. Richardson, M.D., F.R.S., vice-president of the Society, for his paper on "Vital Steps in Sanitary Progress"; Col. Webber, R.E., C.B., Member of Council, for his paper on "Telegraph Tariffs"; B. Francis Cobb, vice-president of the Society, for his paper on "Borneo"; J. M. Maclean, Member of Council, for his paper on "State Monopoly of Railways in India"; W. G. Pedder, Member of Council, for his paper on "The Existing Law of Landlord and Tenant in India."

THE Italian Government proposes to found a central magnetic observatory at Rome, to be placed under the direction of the Meteorological Office. The Government asks for a vote of 176,000 francs, in addition to an annual sum of 5550 francs for general expenses, and 11,500 francs for *personnel*.

THE *Times* Berlin correspondent, telegraphing on Thursday last, states that the reddish-brown atmosphere and the peculiar appearance of the sun and sky which were noticed last year, especially in November, reappeared on the previous evening almost as vividly as ever.

THE results of the analyses made at the Municipal Laboratory of Paris are so satisfactory that tradesmen of that city are holding indignation meetings on behalf of the liberty of watering their liquors and mixing the different kinds of wine. It is needless to state that the public and the administration are equally hostile to any alterations being made in the existing law. But greater precision will now be introduced into the verdict of the experts, and when they declare any liquor to be bad they will state whether it is by adulteration, or alteration of its primitive elements, or mixing with inferior sorts. The development of the institution is so important that forty persons are now engaged in this kind of work. Similar institutions have been created in provincial cities, and a central administration established in Paris. The late M. Wurtz was the head of this useful Bureau; his place is now filled by M. Berthelot.

THE Russian Admiralty has under consideration a plan for an expedition to the North Pole, with a view to benefit by the experience gained by the *Jeannette* disaster. The expedition is proposed to start from the Jeannette, Bennet, and Henriette Islands, where large depots will be established. The journey will be continued thence to Franz-Josef Land by steamer, and further northwards by sledges and on foot. The expedition would be divided into three parties, the first of which would act as a kind of vanguard, the two following not moving forward until suitable camping places had been found and depots established. This system would make the progress safe and systematic. It is estimated that the expedition would require three years to reach the Pole and to return to Northern Siberia. The expenses of the same will probably be covered by a national subscription, the Government, and the Russian Geographical Society.

THE Prussian Government having requested the Swedish to effect measurements of the tide, &c., on the Swedish coasts in the Baltic, similar to those which for some time have been carried out on the Pomeranian coast, Capt. Malmberg and Prof. Rosen have been commissioned to visit the German stations during the summer, and select the most suitable places on the Swedish coast for realising this proposal.

THE Norwegian Storthing has voted the entire sum proposed for scientific and literary purposes—about 5000*l*. Among these we note 150*l*. to the *Technical Journal*, 350*l*. to Dr. Norman's "Flora," 60*l*. to Dr. Sophus Tromholt for prosecuting his auroral researches, 50*l*. each to the *Acta Mathematica* and the "Fauna litoralis Norvegiæ."

AT Weimar, Münich, Elberfeld, and some other German towns have been erected what are called "pyramids of instruction." They show on their various faces the elevation of the place above the level of the sea, the population, the difference of local time from that of Vienna, Paris, London, New York, &c. There are also a clock, barometer, thermometer, vane, and a variety of statistical information.

MR. H. W. EATON of Louisville, Kentucky, writes to *Science* that the *Commercial* of that city for May 17 and 18 gave accounts of a tailed child recently born there. As such cases are of scientific interest, and are very rare, a party of four, including a prominent doctor and Mr. Eaton, concluded to investigate the case. "We found a female negro-child, eight weeks old, normally formed in all respects, except that slightly to the left of the median line, and about 1 inch above the lower end of the spinal column, is a fleshy pedunculated protuberance about 2½ inches long. At the base it measures 1¼ inch in circumference. A quarter of an inch from the base it is somewhat larger, and from that it tapers gradually to a small blunt point. It closely resembles a pig's tail in shape, but shows no sign of bone or cartilage. There seems to be a slight mole-like protuberance at the point of attachment. The appendage has grown in length about a quarter of an inch since the birth of the child. The mother, Lucy Clark, is a quadroon, seventeen years old, and the father a negro of twenty,—both normally formed. In Darwin's 'Descent of Man,' vol. i. p. 28, he speaks of a similar case, and refers to an article in *Revue des Cours Scientifiques*, 1867-68, p. 625. A more complete article is that by Dr. Max Bartels, in *Archiv für Anthropologie* for 1880. He describes twenty-one cases of persons born with tails, most of them being fleshy protuberances like the one just described."

ON May 27, at about 8.45 p.m., immediately after sunset, a magnificent meteor or fireball was seen at Skonevik, on the west coast of Norway. It went in a perfectly horizontal line to north-north-west, leaving a bright tail behind appearing like steam. This trail was distinctly observable for quite five minutes, when it gradually spread in the shape of a light cloud, which was soon hidden in the approaching darkness. About two minutes after the ball had passed out of sight a loud report was heard in the same direction; it was very much like ordinary thunder heard from a distance, with the exception of its lasting twice as long. The sky was perfectly clear, and several persons witnessed the phenomenon. The meteor was also observed in the Kvinherred parish.

ANOTHER "blue grotto," or, rather, series of three large grottoes, 87 metres in length, has been discovered on the Dalmatian island of Buoi, lying to the south-west of Lissa. The cave is described by its discoverer, Baron Ramsonnet, Austrian Secretary of Legation, as surpassing the famous Capri Grotto.

THE additions to the Zoological Society's Gardens during the past week include two Macaque Monkeys (*Macacus cynomolgus* ♀ ♀) from India, presented respectively by Mr. Howard Lane and Madam Kettner; two White-fronted Capuchins (*Cebus albifrons* ♂ ♀) from South America, presented by Mr. Messum; a Coypu (*Myopotamus coypus*) from South America, presented by Mrs. Constance Keely; a Harpy Eagle (*Thrasaetus harpyia*) from South America, a Red-billed Tree Duck (*Dendrocygna autumnalis*) from America, presented by Capt. H. King; a White-tailed Buzzard (*Buteo albicaudatus*) from America, presented by Mr. Lewis; a Wedge-tailed Eagle (*Aquila audax*) from Queensland, presented by Mr. Henry Ling Roth; two Choughs (*Pyrrhocorax graculus*), British, presented by Mr. J. Compton Lees; a Gray-breasted Parrakeet (*Bolborhynchus monachus*) from Monte Video, presented by Mrs. Moore; two Cape Crowned Cranes (*Balearica chrysopelargus*) from South Africa, presented by Mr. J. R. Chapman; a White Stork (*Ciconia alba*), European, presented by Mr. Hubert D. Astley; a Partridge (*Perdix cinerea*), British, presented by Mr. George Rubie; a Blue and Yellow Macaw (*Ara ararauna*) from South America, deposited; a Brush-tailed Kangaroo (*Petrogale penicillata*) from New South Wales, four White Storks (*Ciconia alba*), three European Pond Tortoises (*Emys europæa*), European, a Common Boa (*Boa constrictor*) from South America, purchased; a Black-necked Swan (*Cygnus nigricollis*) from Antarctic America, received in exchange.

OUR ASTRONOMICAL COLUMN

THE OXFORD UNIVERSITY OBSERVATORY.—The Savilian Professor of Astronomy has issued his Annual Report to the Board of Visitors of the University Observatory, which was read on the 5th of the present month, and forms a supplement to No. 493 of the *Oxford University Gazette*. The attendance of students at the lectures has been greater than at any previous time, and the Professor mentions "the phenomenon" of the regular appearance of two ladies at his lectures on the planetary and lunar theories, at the same time reminding the Board what even the approximate mastery of such theory implies.

On the astronomical work of the staff of the institution during the year, Prof. Pritchard's Report is a most favourable one. He refers to three memoirs on important astronomical questions which have issued therefrom, and which have been printed in the *Memoirs* of the Royal Astronomical Society. These include an extensive memoir by himself on the "Photometric Determination of the Relative Brightness of the Brighter Stars North of the Equator," in which his work at Cairo is brought to bear, and a memoir by the first assistant, Mr. W. E. Plummer, on the probable motion of the solar system in space, the data for which depend upon Mr. Stone's recent catalogue of southern stars; it is a memoir very similar in character to the well-known one by the late Mr. Galloway. Further, Prof. Pritchard has communicated to the Royal Astronomical Society a paper which was read at the last meeting, demonstrating, as he thinks, the existence of small displacements among the Pleiades. Upwards of a thousand measures of the relative brightness of stars were made, leaving about the same number to be made in the next year. This measurement of all the naked-eye stars from the Pole to the Equator will furnish a *Uranometria Nova Oxoniensis*, and Prof. Pritchard hopes that its publication may be undertaken by the University Press. The measures of the Pleiades having been completed, he now intends to devote himself to lunar work—the determination of selenographical longitude and latitude of a large number of points on the moon's surface by means of a valuable series of lunar photographs at the Observatory. Reference is made, in addition to the Pleiades work, to the existence of measures of some 250 stars in another cluster made at the Observatory a few years since, and to be shortly reduced and published; the particular cluster is not indicated in the Report, but presumably may be M. 39 in Cygnus, described by Messier when he observed it in 1764 as "a star-cluster of 1° diameter."

VARIABLE STARS.—In a communication to the Liverpool Astronomical Society Mr. Baxendell notifies that his determinations of the times of eight maxima between 1861 October 16 and 1881 November 21 are not satisfied by a constant period, but that, dividing them into two groups, he obtains the following results:—

Group 1. Mean period 206·37 days. Ep. 1864 Jan. 17·47.
Group 2. Mean period 212·52 days. Ep. 1880 Sept. 24·21.

Such a difference is well worthy of further investigation. The magnitude at maximum has varied between 7·8 and 9·3.

There does not appear to be any earlier observation of this star than that by Bessel on January 6, 1833, when it was estimated a ninth magnitude. It was not observed either by Lalande or D'Agelet. Prof. Schönfeld's elements in his second catalogue, which assume a uniform period of 208·8 days, would give a maximum on October 6, 1881; according to Mr. Baxendell, it took place on November 21.

Communications from Mr. Knott and Herr Wilsing, of the Observatory, Potsdam, on Ceraski's short-period variable, U Cephei, have appeared in the *Astronomische Nachrichten*. Mr. Knott, from 20 minima observed by him between 1880 October 23 and 1884 March 20 finds for elements—

Ep. 1882 April 19·92641 G.M.T. + 2·4928722 d. E.

Herr Wilsing has collected 61 minima by different observers between 1880 July 3 and 1884 April 9, and finds (similarly expressed)—

Ep. 1881 Nov. 21·34640 G.M.T. + 2·4928646 d. E.

To the suspected circumpolar variables recently named in this column may be added Bradley 392, which figures in our catalogues with various estimates of magnitude from 4·5 (Argelander's Zones) to 7 and 8 (Taylor and Lalande); generally, however, it has been called a sixth magnitude. Doubtless in many, perhaps in most, cases, such discordances arise from errors of estimation, through clouds, &c., or from misprints, but in others, as in the case of Schwerd's magnitudes of U Cephei (6·7, 8, 10 respectively), they are known to have been caused by a real fluctuation in the star's brightness, and hence it seems worth while to examine similar instances of disagreement in the catalogues.

MISSING NEBULÆ.—In Rümker's Catalogue are two objects observed as nebulæ which were missed by D'Arrest and Auwers. In No. 1542 of the *Astronomische Nachrichten* Mr. G. Rümker has given the particulars of the observations from his father's manuscripts. The first nebula was observed on May 27, 1841, and its apparent place was R.A. 13h. 52m. 38·20s., Decl. + 45° 36′ 13″·8. The Hamburg mean time of the observations was 9h. 31m. 43s. In the *Durchmusterung* we find a star thus—

8·8 ... 13h. 53m. 10·0s. + 45° 31′·7 ... R.

Consequently Argelander identifies this star 8·8 m. with Rümker's nebula. Two questions arise in such a case, and not for the first time: Was a comet projected on the place of Argelander's object at the time of Rümker's observation? or (more improbably), Was the star at that time surrounded by nebulosity which has since become invisible? Bessel, we know, observed a nebulosity on November 8, 1832, in a position where only a star 9·3 m. was subsequently seen by Argelander and D'Arrest. We refer to Rümker's first nebula more especially because its place was not very far from that which might have been occupied by the third comet of 1858, recently shown to be periodical by M. Schulhof. If that comet were at perihelion about 1841 April 21·8, its right ascension might have agreed with that of Rümker's nebula, but the declination would be given by calculation about 6° further north. Whether with the consequent period of revolution, which, assuming three periods, 1841–58, would be near M. Schulhof's lower limit, the action of the planet Jupiter during the first revolution could have caused such difference from the orbit for 1858 as to reconcile the discordance in the observed and computed declination, we cannot say, though it hardly appears likely. Still it may be worth while to mention the above approximate coincidence, as M. Schulhof has searched unsuccessfully for an indication of a former appearance of the comet in question.

GEOLOGICAL NOTES

TRICLINIC PYROXENE.—Mr. J. J. Harris Teall points out to us that since the paper was written on this subject by Mr. Whitman Cross, to which reference was made in NATURE (*ante*, p. 155), this author has found that, after reconsidering the matter in the light of the researches of Fouqué and Michel Lévy on the optical properties of monoclinic pyroxene, a great majority of the instances cited by him as indicating a triclinic pyroxene are explainable as augite, and that the few cases which still seem anomalous are not in themselves sufficient to justify a reference to the triclinic system. The mistake was made in specimens not cut rigidly parallel to the axis, for it appears that the ellipsoid of elasticity is so situated as to produce very great variations in optical behaviour in sections which are but little inclined to each other. [*Amer. Journ. Science*, No. 151, xxvi. p. 76].

THE BRUSSELS MUSEUM AND ITS WORK.—The second volume of the *Bulletin of the Musée Royal d'Histoire Naturelle de Belgique* has just been completed by the issue of a fourth fasciculus. In this part geology and palæontology continue to assert their supremacy. M. Dollo supplies a paper on a gigantic fossil bird (*Gastornis Edwardsii*, Lemoine) from the lower part of the Landenian stage at Mesin, near Mons. Having completed the summary description of the Iguanodons, but not being yet in a position to publish his expected large monograph on that important group, he has in the meantime turned to the Crocodilians of Bernissart, of which he furnishes here a preliminary notice. They consist of four individuals capable of division into two well-marked groups—two large specimens indicating an animal about two metres in length, to which he gives the name of *Goniopholis simus*, and two small forms which he regards as belonging to a new genus, named by him *Bernissartia*. M. Ernest Van den Broeck, following up the memoir published in a previous number of the *Bulletin* by his colleague, M. A. Rutot, offers a note on a new mode of classification and of graphic notation for geological deposits, based upon the study of marine sedimentation. The veteran palæontologist, Dr. L. G. De Koninck, contributes an essay on the *Spirifer mosquensis* and its affinities with other species of the same genus.

GEOLOGICAL SURVEY OF BELGIUM.—Appended to the last number of the *Bulletin of the Musée Royal* is a Report by M. Dupont, Director of the Museum, on the state of the detailed geological map of Belgium, which is being prepared under his supervision. The preliminary examination, which was estimated to require six years, having been completed, the continuous survey of the formations has been prosecuted, each important group being intrusted to an officer specially qualified for its investigation. Nineteen sheets are in the course of preparation for publication. Of these the greater number belong to the remarkable Devonian territory which forms so interesting and important a part of Belgian geology. We see from the map that these sheets are mainly the work of M. Dupont himself. He spent 100 days in the field last year almost entirely among the Devonian rocks. M. Mourlon devoted his time to tracing the area of the Famennian beds. The third section, under the charge of M. Van den Broeck, has made progress among the oligocene Tertiary deposits of Central and Northern Belgium. The fourth section, supervised by M. Rutot, spent half of the season in mapping the Eocene deposits of Limbourg, and the remainder in prosecuting the investigation of Hainault, Brabant, Flanders, and the study of the Upper Cretaceous rocks and base of the Eocene series, the Eocene part of three sheets being finished. Dr. Purves, in charge of the fifth section, has devoted his energy to the mapping of the Jurassic rocks of Luxembourg, and the study of the Cretaceous series of Hainault and Limbourg. The total number of days spent in field-work by the whole staff has been 512.

GEOLOGY OF FINMARK.—Mr. Karl Pettersen continues his contributions to our knowledge of the geology of the Norwegian coast. In a recent memoir (*Archiv for Math. og Naturvidenskab.*, Bd. viii. p. 322) he describes that picturesque tract lying between the mouth of the Kvenangen Fjord and the Refsbotten, which includes the lonely Jökelfjord and Bergsfjord with the islands of Stjernö, Seiland, Sörö, and Kvalö. The greater portion of this area is occupied by various crystalline rocks—gneiss, mica-schist, gabbro, diorite, &c.—referred by the author to the Laurentian series. Above these lie certain certain mica-schists with included beds of limestone, which, under the name of the Tromsö mica-schist group, are assigned to the Cambrian system.

AMERICAN JURASSIC DINOSAURS.—In the *American Journal of Science* (April 1884) Prof. Marsh continues the valuable series of papers which he has contributed to our knowledge of the structure and affinities of the Jurassic Dinosaurs. In part viii. he discusses the carnivorous order Theropoda, two nearly perfect skeletons belonging to which have enabled him to throw some new and most important light on the order. An almost perfect skeleton, above seventeen feet long, has been named by him *Ceratosaurus*, and presents some novel features in dinosaurian organisation. It has a large horn on the skull, a new, strange,

and unexpected type of vertebra, a pelvis with all the bones co-ossified as in existing birds, and a set of osseous dermal plates extending from the base of the skull along the neck over the vertebræ.

Geological Survey of New Zealand.—Dr. Hector's Report for 1882 has just been received. It contains some additions to our knowledge of the geological structure of the country, but these do not involve any marked alterations in the system of classification already adopted for the formations, but rather tend to establish its general applicability. The Report is specially characterised by the attention paid to the development of the mineral resources of the colony. Mr. S. H. Cox, in compliance with specific instructions, made a careful examination of the gold-fields of the Cape Colville Peninsula and of other mineral tracts, while Mr. A. McKay reported on some antimony and other lodes. The geology, petrography, and palæontology of the islands have likewise received attention. The schists of the Reefton district are regarded as a metamorphic series of Silurian age, as they can be traced into fossiliferous Silurian strata. The granite-porphyries by which they are traversed were intruded into them subsequent to the Devonian rocks. The metamorphic series is covered in some places by the Devonian beds, from which fossils have been obtained at a number of new localities. The auriferous rocks of Reefton are referred to the Matai or Carboniferous formation, and are believed to lie unconformably on the younger Devonian rocks. The Cretaceous and Cretaceo-Tertiary series form a continuous sequence in which coal has long been known to occur. Seams of coal, four to ten feet thick on an average, characterise certain horizons, one seam at the head of the Murray Creek reaching even to thirty or forty feet. The coarse sandstones and grits among which the coals lie are represented as being conformably overlaid by Miocene gravels.

The Austrian Geological Institute.—This admirable organisation, under the energetic management of its Director, F. Ritter von Hauer, shows no sign of any diminution in its activity or of any lessening of the wide scope of its labours. Among the recent numbers of its *Verhandlungen* some interesting papers have appeared, of which may be mentioned: A. Bittner, on the Limestone Alps of Salzburg; E. Tietze, on the occurrence of turquois in Persia; V. Hilber, on the geology of the region between Krzyzanowice and Tarnobrzeg; D. Stur, on some fossil plants from South Wales; A. Böhm, on geo-isothermal lines under mountains. The last two numbers of the *Jahrbuch* are full of important memoirs. Among these reference may be made to Bittner's Report on the survey of the Triassic region of Recoaro; Paul's "Recent Additions to our Knowledge of the Carpathian Sandstone"; Dr. Tietze's essay on the geology of Montenegro, and the continuation of his contributions to the geology of Gallicia.

ON NORTHERN NORWAY UNDER THE GLACIAL AGE

The Stream of Inland Ice.—From the broad sound between the Kval Island and the province of Finmarken, from which the Troms Island juts forth, the Kval Sound—about 20 km. in length—leads to the open ocean. Outside the Kval Sound several little islands rise from the sea, while beyond the coast is girded by holms and rocks termed the "Skjærgaard." A little south of the Troms Island the Balsfjord, about 60 km. in length, cuts into the land, closed at the bottom by small ridges leading up to the valley in which the Maals River flows, and to the borderland between Norway and Sweden, chiefly through the long Divi Valley. The borderland embraces large mountainous tracts, where peaks rise to an elevation of 1569 m., crossed by dales and high valleys.

In the district described, the local conditions during the Glacial age seem to have been remarkably suited to the formation of large masses of ice. These would have their natural outlet towards the Maals River, through the Divi Valley, and the main stream has no doubt therefrom flown down the Maals Valley, but an arm may have curved more to the north along the northern slope of the Mauken ridge, and by ice-streams from this and from the gigantic high plateaux around the Maar peaks down to the bottom of the Balsfjord. From here the joint stream would have moved further forward to the sounds along both sides of the Troms Island, and thence, through the Kval Sound, over the islands in the Skjærgaard. The channel described has a length of 215 km.

As is generally known, the inland ice of Scandinavia is assumed to have shot far beyond the edges of the peninsula. Thus from Southern Norway the inland ice is believed to have moved forward along the fjords, and filled the entire North Sea as far as England, while further north it has been curved in a more northerly direction, by the ice-streams issuing from Scotland, towards the Orkneys and the Shetlands. It might be supposed that similar conditions existed during the Glacial period in the north of Norway; but from what is known at present there is nothing indicating that the Glacial age has appeared in a more severe form in the southern than in the northern part of Norway; it seems, in fact, from the geographical situation of the land, that the reverse must have been the case. There are besides, as I will presently show, indications which seem to demonstrate that the ice-masses of the Glacial age, at all events in certain parts of Northern Norway, have attained an extent which equals those of Southern Norway, as, for instance, those along the Sognefjord, 1700 m. to 1800 m. in depth. On the high plateau behind the Divi Valley, close to the frontier, the cone of the Great Jerta, built of amphibolitic slate, rises to a height of 1569 m. Nowhere have granite strata been found intercepting this slate. On the top of this peak a large travelled granite block was found, which in most probability has been transported thither from the extensive granite field which stretches forward on both sides of the frontier. The ice which has moved down the Divi Valley must therefore have been very nearly 600 m. in depth.

There seems every reason to suppose that the channel from the bottom of the Balsfjord to the Skjærgaard has, during the Glacial age, boasted a comparatively uniform depth; and, supposing the sea to have been about 188 m. higher than at present, this channel would nowhere have been deeper than 470 m. An ice-stream moving forward by this channel, and which probably had a thickness of 1600 m., must have moved forward along its bottom, and most probably with a quick motion. If the ice-streams from the south-west of Norway have, as assumed, moved forward, and filled not only the fjords to the bottom, but the entire North Sea to England, we may conclude that this should also have been the case in the channel in question during the Glacial period. If this has been so, marked traces of such an ice-stream would, no doubt, have been visible from the very bottom of the Balsfjord right out to the Skjærgaard; but the researches made here point in a different direction. I will elucidate this by following the channel referred to *from* the ocean coastwards.

About 11 km. from the mouth of the Kval Sound, in the open ocean, lies the little Ris Island, surrounded on south, west, and north by a great number of tiny islands, reaching a height of 100 m. It is formed of a ridge running north to south, in the west sinking abruptly into the sea, but which in the east sinks into a low-lying plain, from which several isolated knolls spring forth. Several of these knolls are connected with the main island by sand dunes, and have most probably at no distant time formed separate holms. Most of the numerous holms surrounding the Ris Island are small, and only rise a few feet above the water. The mineral of which this group of islands is formed is a hard kind of gneiss, greatly interspersed with granite more or less pure; the mineral is, in fact, with its petrographical variations and forms, rather to be considered a kind of granite-gneiss, a name which is given to it in these parts. The strike of the granite strata is, roughly speaking, north to south, with a sudden dip to the east. By its structural condition this mineral should be greatly affected by smoothing and polishing agencies, and also retain the traces of such. Should, therefore, the inland ice at a certain period have moved forward along the Kval Sound, the group of islands around the Ris Island would undoubtedly bear the most patent indications of this action. The polishing phenomena are often met with at lower levels, which either lie within the littoral belt, at high tide under the sea, or rise only a few feet above high tide, but with the sea continually washing over them. At higher elevations these phenomena are rarely discovered. Here severe destructive forces have been at work on the previously polished surfaces, and the numerous sea-birds breeding on these islands have further contributed to the corrosion.

Several circumstances seem, however, to indicate that the polishing in question cannot be referred to the scourings of the ice in the Glacial period, but is of a far later date. The rapid destruction seems in fact to demonstrate that the smoothing must be referred to agencies of shorter duration. The smooth,

ings which are shown—certainly not very marked—seem to point in this direction, while the smoothing along the lower levels of the holms referred to above are generally met with more in the parts most exposed to the fury of the sea than inland. The smoothing appears but rarely in spots on the lee side of the ocean, even where they might be assumed to have been very exposed to the glaciers. I have therefore come to the conclusion that the smoothing phenomena observed here must be ascribed to the erosion of the sea, which, under its action in the littoral belt, carries with it finer as well as coarser materials of scouring. Striæ have nowhere been observed on the Ris Island or the surrounding islands.

If ice-streams from the southern part of the Scandinavian peninsula have carried blocks from the mountain plateaux of Sweden and Norway across the Central European plain to England, to the Orkneys, and the Shetlands, an ice-stream moving along the Balsfjord and further along the channel described above through the Kval Sound should naturally have progressed in the same manner, and strewn blocks along its whole course. This is, however, not the case. On the Ris Island, thus, and surrounding islands, not a single boulder or travelled block whose place of birth could have been on the upland behind has been found. The mountains along the Balsfjord and towards the Troms Island is mostly built of slaty minerals, such as glimmer-slate (interspersed with crystalline chalk), quartz, sandstone-like slate, &c. Such minerals might have been greatly subjected to being ground away during a longer transport, and that travelled blocks of this kind are not found might be ascribed to this circumstance; but among the travelled blocks strewn over the Central European high plateau there are found also many of slate, which are supposed to have been transported thither from Scandinavia, and if these have been able to resist the destructive agencies during such a long transport, they would decidedly have done so here where the distance is so short.

Among the softer minerals forming the mountains from the Balsfjord there frequently occur strata of harder nature, as, for instance, of gneiss, massive amphibolites, and eclogites, while Saussurite appears in the bottom of the fjord. There are minerals whose composition would enable them to resist the severest destructive agencies even during the longest journey. The total absence of foreign travelled blocks on Ris Island and adjacent holms is therefore hardly to be reconciled with the supposition that continuous streams of ice from the inland moved thither. Neither is moraine drift met with about the archipelago in question.

Just north of the Ris Island, the Sandviks Island, 407 m. in height, rises above the sea. Along the whole eastern side extensive accumulations of sand containing marine shells are met with to a height of 63 m. In the higher-lying layer the sand is, however, poor in such remains, although fragments may be found at an elevation of 56 m. Here it seems as if the coast districts must have been earlier denuded of the local glaciers of the post-Glacial period than the upland behind. Along the Troms Island and the adjacent district the shell-bearing layer of sand is never found above 13 m., while in the clay deposits along the rivers fossil shells are never found at a higher elevation than 38 m. The Troms Island has, however, at a time when the sea in relation to the rock was 40 m. higher than at present, been greatly covered by local glaciers, while the coast district beyond must have been almost free from such. The conditions for the development of a more copious fauna of mollusks have thus existed along the outer coast *earlier* than in the fjords behind. It appears therefore that during the transition from the Glacial to the post-Glacial period the milder climate has spread from the sea *coastwards*, although, as it seems, very slowly.

We now turn to the district behind the channel referred to, particularly to the little Troms Island, where there has been special opportunity of examining these indications. The island is 11 km. long and 157 m. in height, and, lying just in the flow of the ice-stream, was situated so that the travelling glaciers should have left lasting traces on it. By a cursory glance the glacialist is led to believe that the markings must be referred to the streams of inland ice, particularly as the island is all along the southern part, at higher as well as at lower elevations, covered with a layer of drift from the "ground" moraine several feet in thickness, while old boulder drift-wolds may be seen in several places. Besides this, foreign travelled blocks are strewn in great numbers along the sides of the island, while striæ appear in many places along the littoral belt and adjacent levels. A closer examination will, however, put these indications in a different light. Thus, with regard to the boulder drift, it will be found that most of the stones and blocks embedded in the same belong to the island itself, and none can with certainty be asserted to have belonged to mountains beyond the island. These drifts must therefore be ascribed to local glaciers, which at one time partly covered the island. With regard to the striæ, which appear in some places at lower levels, I am of the opinion that they were made in what is at present the littoral belt. Foreign travelled blocks, *i.e.* those consisting of various species of granite, are, as stated, only found here at low levels, viz. from the present seashore to an elevation of 38 m. These blocks have, however, I believe, been transported thither by floating glaciers. The elevation, even, in which they are found, indicate that the transport of these foreign blocks can only have begun at a period when the more continuous layers of inland ice were broken up.

The district along the Balsfjord is, on the other hand, to a great extent built of the same kind of crystalline slate rocks which form the Troms Island, and it is therefore impossible to deny with certainty that there are boulders in the drift which have been carried from the land behind. But there is another circumstance which I believe will make this point plainer still. Between the minerals of the district around the Balfsjord there is, as stated above, also a stratum of Saussurite gabbro, which at the bottom of the fjord is of enormous thickness. The Saussurite gabbro is a remarkably tough rock, especially qualified to resist the destructive agencies under a long transport. Should therefore a continuous stream of ice at one time have moved forward along this fjord and its bottom, there seems every reason to assume that fragments of Saussurite gabbro would have been carried with it and now be found along its track, which should particularly be the case with the Troms Island, more advantageously situated for receiving the same than any other spot. But in spite of the most careful search the scientist has not succeeded, either between the loose, solitary blocks or in the Glacial drift here, in discovering a single fragment of Saussurite gabbro. There is, therefore, every reason to assume that the ice-streams which moved down the Balsfjord cannot have reached the Troms Island.

If this conclusion be correct, traces of the Balsfjord ice-stream will not be found along the channels outside, *i.e.* north of Tromsö, viz. neither in the Kval Sound nor in the others in which the ice moved to the sea. There has not been any opportunity of proving this, but from impressions during my frequent journeys along these inlets, I can with confidence assert that no travelled blocks will be found here either whose birthplace was on the upland behind.

A few years ago I examined the greater part of the mouth of the Balsfjord, and I have neither there observed travelled blocks which were transported from the bottom of the fjord. I have therefore come to the conclusion that the continuous ice-stream of the Glacial period cannot have reached beyond the basin of the fjord.

From the premises thus set forth we may draw the deduction that the inland ice in North Norway during the Glacial age did not move forward along the above-described line, viz. through the sounds to the ocean, while we may presume that neither did they travel through the Balsfjord.

By the foregoing line of argument the conditions of Northern Norway must have differed greatly from those which we assume prevailed in Southern Scandinavia under the Glacial period. These two deductions, so much at variance, lead to the following conclusions: (1) That either the Glacial period must have appeared in a far severer form in the southern than in the northern part of the peninsula, or (2) that the conclusions here arrived at are based on an erroneous construction of the evidence presented to us.

With regard to the first of the points, I have already pointed out that every sign seems to indicate that somewhat similar conditions prevailed throughout the Scandinavian peninsula during this period. If thus the inland ice in Northern Norway was not powerful enough to move to the ocean along the sounds, there is but little probability of the conditions having differed in this respect in the southern part. And if, on the contrary, this has been the case in the southern half of the peninsula, there is every reason to suppose that it was so also in Northern Norway, and that ice has moved coastwards, scouring the surface wherever the depth permitted. It seems, therefore, necessary to assume that

the second suggestion is correct, and that erroneous conclusions have been arrived at. There seems, for instance, reason to suggest that these deductions, even if logically correct for the district delineated, may not apply to the entire northern half of Norway in general before they have been more extensively corroborated. As to this suggestion, I may reply that the district described above comprises a great area. It includes thus channels of continuous fjords and sounds close upon 120 km. in length, and a coast line 90 km. long, and what is most important, that the channel in question is one which, by the orographical structure, has offered one of the most suited channels for the flow of the ice. If the inland ice has not been powerful enough to move forward by this channel, there is, I believe, little probability of finding a single similar channel in Northern Norway in the district between Salten and the North Cape by which the inland ice has moved to the coast.

If, on the other hand, the southern part of the Scandinavian peninsula is examined, where the inland ice is supposed not only to have filled the fjords but also the entire North Sea and the Baltic, such a circumstance presupposes, in my opinion, conditions so gigantic that they may even from the first be doubted. In fact, the area of the snowfall from which these enormous masses of ice must have been originated is not proportionate to the supposed results. Anything corresponding with such a result is not to be found even within the Arctic zone, which at present suffers most from glaciation. The Polar basin itself is, I believe, nowhere filled with ice masses, which reach the bottom. It is, in my opinion, filled with sea ice in constant drift.

My deduction is, therefore, that the theory of the ice-streams from the Scandinavian peninsula having advanced and covered the North Sea, the Baltic, and reached the Central European plain, England, the Orkneys, and the Shetlands, cannot with the facts at our disposal be accepted as a scientific doctrine.

Travelled Granite Blocks in the Neighbourhood of Tromsö.—Of the loose blocks and boulders which are found in such large numbers about this town, partly embedded in the sand, and partly in old moraine drift, or strewn over the ground, the greatest number had their origin in the solid mountains in the vicinity. These may, as we may have reason to assume, be found at the most different elevations, as the agencies which produced them have been in continuous action down to our time. Real travelled blocks, transported to their present place from a distance, appear also in quantities in this district, but the latter seem to be confined to certain levels. Of these foreign kinds of travelled blocks, most are of granite, and I draw particular attention to these, not only on account of their frequent occurrence, but also from their great dimensions, a great many being thus from a half to one cubic metre, and more. These blocks are mostly rounded, without, however, showing any greater polishing. Striæ are never found on them.

They appear in greatest number up to a height of 25 to 30 m., and more seldom between 30 and 38 m. Up to the former height they are everywhere to be found, while in higher elevations they are difficult of discovery. The line of demarcation upwards is pretty distinctly defined, but the blocks are not always to be found to the above height. There are lines along which the granite blocks are heaped up to this height, and beyond they suddenly disappear. The change is so startling that attention is at once arrested. It should, however, be stated that the line mentioned at 38 m. very nearly answers to the level of the shore line graven in the solid rock, which, greatly pronounced in this place, may be traced for miles.

During the summer of 1882 I carefully examined these conditions, paying the most minute attention to the two sides of Troms Island, 11·3 km. in length, whence I extended my researches along the sounds on both sides of this island, viz. southwards to the tracts about the mouth of the Balsfjord, about 11 km. in length. But while the travelled blocks will be confined upwards to certain levels, no such demarcation will be found downwards. They are to be found down to the lowest level of the littoral belt. Particularly there will within this belt often be found heaps of large blocks ranged in rows along the central tide line, *i.e.* the line marking half tide. On the Ren Island, too, some eighteen miles north of Tromsö, I found once a great number of granite travelled blocks strewn along the lower levels in a line from south to north. With the exception of certain parts of Kvals and Ringvats Islands, the mountains along this district will nowhere be found to consist of granite, neither will there be found strata of granite nature to which these travelled rocks might be ascribed. I must, of course, admit that a series of continuous researches are certainly required before it is possible with certainty to fix the place of birth of these blocks. With the materials at present at our disposal, however, we may arrive at some safe conclusions.

The granite field nearest from the sea inland is found far up in the Divi Valley. Of other granite strata inland there cannot here be a question.

This granite field is 124 km. from the Troms Island. Nearer than the above-described district is, however, the coast with extensive strata of gneiss-granite, which appears particularly prominent over the Kval Island situated just west of the Troms Island. From either of these the travelled blocks must have their origin.

If, now, the Divi Valley is accepted as their place of origin, the transport has been effected from the inland coastwards. If, on the other hand, the Kval Island is designated as their place of production, the transport must have taken place in opposite directions, viz. *from the coast landwards.*

If we now examine the petrographical composition of the travelled blocks, a great many will be found to be formed of varieties which belong to the gneiss-granite of the coast. But there may, on the other hand, be found many blocks among them which seem petrographically to be less related to the gneiss-granite, but to resemble typical inland granite far more.

At first sight, therefore, one would conclude that the travelled blocks might have been brought by both named roads. In this respect I must, however, point out that the gneiss-granite of the coast may petrographically vary considerably, and that it may be interspersed by or run into granite of purer character. In spite even of the greatly varying petrographical forms under which the travelled granite blocks may appear in the neighbourhood of Tromsö, I do not therein see any reason for denying that the travelled blocks may in general have their origin from the gneiss-granite. There are, however, several circumstances which tend to refute the theory of the blocks having been moved thither from the granite fields in the Divi Valley. If the blocks were thus carried down to to the Troms Island and adjacent sounds, it must have been effected in either of the following ways:—

1. Either from the upper part of the Maals River across the mountain ridges down to the bottom of the Balsfjord, and thence outwards to the Troms Island.

2. Or along the bed of the Maals River to the bottom of Malangen, and thence further through the sounds which here run in an easterly direction towards the Troms Island, between the mainland and the southern side of the Kval Island.

And here I must point out that the granite stratum in the Divi Valley appears with its western edge at a height of about 188 m. above the sea. The Divi River runs, however, into the Maals River at an elevation of about 78 m. above the sea, while the bottom of the Balsfjord is separated from the Maals Valley and thus also from the Divi Valley by a higher mountain ridge in which the deepest insections, tending towards the Balsfjord, lie at an elevation of about 160 m., *i.e.* about 78 m. *higher* than the conflux between the Divi and the Maals Rivers. If, therefore, the blocks from the Divi Valley travelled down to the bottom of the Balsfjord, they must have done so over passes which lay 78 m. higher than the conflux between the two rivers! Although it might be most natural to assume that the ice-streams of the Divi Valley followed the bed of the Maals River, the suggestion that an arm from the same might have moved over the higher ridges down to the bottom of the Balsfjord is certainly one which cannot be ignored. But, if this was the case, the granite blocks which had been carried from the Divi Valley in this way ought to be found at the bottom of the Balsfjord at a higher elevation than 30 m. above the sea. Whether travelled granite blocks will be found at the bottom of this fjord is a question which cannot be answered, as but little attention has yet been paid to the same. I am, however, of the opinion, from my own investigations, that they are totally absent in this place.

If granite blocks were, on the other hand, carried down into the Balsfjord by this road, they must, judging by the height to which they are found near Tromsö, have been carried from this place further by drift ice. The beginning of the transport belongs thus to a period when the real Glacial age was closed, and the continuous ice-layer broken up. In this case it might be assumed that the travelled blocks should be found in largest numbers along the sides of the Balsfjord, and decreasing in numbers from the bottom of the fjord outwards to

Tromsö. On this point, too, we are without conclusive proofs, but the examinations have, as already stated, been extended inwards to the mouth of the Balsfjord and its environs, and the results of these disprove such an assumption. Granite blocks are thus to be found about the mouth of the Balsfjord, but in far lesser numbers than over the Troms Island. It is just on the southern part of this island that travelled blocks are found in largest numbers in the whole district; while the circumstance that neither blocks nor fragments of Saussurite gabbro, which, as pointed out, are found in enormous quantities in the neighbourhood of the Balsfjord, can be discovered among the travelled blocks on the Troms Island, further corroborates my belief that no transport of blocks from the Balsfjord outwards to the sea has taken place. In fact, I am fully convinced that the block-transport has taken place *from the coast inwards.*

There is thus every reason to believe that the travelled granite blocks have not been carried out to the Troms Island through the Balsfjord. In fact, there seems more probability that the transport was effected through the Maals River. But, if this was so, travelled granite blocks would have been found on the slopes of the Malang, and here too in decreasing numbers *from the inland towards the outer islands,* which appears, however, not to be the case. I have therefore come to the conclusion that the birthplace of the travelled granite blocks in the vicinity of Tromsö must be referred to the gneiss-granite stratum of the coast, and thus again chiefly to that part of the same which appears at the Kval and Ringvats Islands west of Tromsö. This assumption is supported too by the circumstance that a great number of the travelled blocks, judging by the petrographic composition of the mountains in question, undoubtedly belong to the gneiss-granite of the coast, and that there is nothing to disprove the theory that even the blocks which petrographically seem to differ in composition also belong to the same stratum in composition.

The highest elevation in which the travelled blocks are found in the neighbourhood of Tromsö indicates that the transport of the same has taken place *after* the close of the Glacial period, *i.e.* in an age when the continuous layer of the Ice age had broken up into more or less separated glaciers. Under these circumstances the transport of the blocks from the Kval Island inwards to the Troms Island *must have been effected by floating ice.* The highest line of elevation in which the blocks along the sounds are deposited *indicates, therefore, the height of the sea at the commencement of the block-transport.* And as the blocks are often found in greatest number somewhat below this line, I have come to the conclusion *that block-transport has progressed more rapidly as this period advanced.* I may, however, add that the whole epoch of the block-transport has probably been a short one.

The local conditions of Kval Island seem also to have greatly favoured even the most extensive block-transport at an early age. The continuous layer of ice of the Glacial period has thus, as demonstrated above, been broken up thus early, that the ice remained only in local glaciers of great extent. So early must the block-transport have taken place also in an easterly direction, both through open channels of the Balsfjord and the Kval Sound, and unimpeded by the ice-streams moving down from the mainland. When, however, this, as appears from the blocks in the neighbourhood of Tromsö cannot have been the case, at all events to a limited extent alone, there is herein an obvious proof that special conditions which favoured the current carrying the blocks to the shore did not exist before the epoch which corresponds with the highest level in which the blocks are found.

If the blocks were, as I believe is demonstrated beyond doubt, transported to their places by floating ice, the flow of the currents must have greatly influenced the direction of the block-transport. At a period, therefore, which is determined by the transport commencing eastwards, special conditions must have existed which have caused a stronger flow of the current from the outer coast inwards. There are, in fact, several circumstances which seem to point in this direction. There is in particular that of the Gulf Stream. It is thus evident that the Gulf Stream, which during the Glacial age was diverted from the coast of North Norway, has, in a comparatively recent era, curved towards the coast to a considerable extent.

As is generally known, a complete Arctic Sea fauna existed along the coast of Norway in the early part of the Quaternary age; but by degrees this has been more and more mixed with southern species, an encroachment which continued without interruption to the present time, and is, I believe, still in full operation. Some perfectly pure species of the Arctic fauna may still be met with in some of the deepest fjords of Norway, but even these remains are most probably in retrogression. This constant retrogression of the original Arctic Sea fauna on the coast, and the encroachment of a more southern, must naturally be dependent on currents of warm water coming from the south, and as long as the Arctic fauna alone supervened, these warm currents must have been entirely absent from the coast line referred to in this paper. From the moment access was made for the same, the southern fauna began to manifest itself. In the block-transport here described, which began at a period when the surface of the sea lay, in relation to the fundamental rock, about 30 m. higher than at present, I believe we may find a more exact determination of the time when this curve in the current took place.

There is, besides this circumstance, another of equally great importance which points in the same direction. It is a fact, thus, that fragments of pumice-stone are constantly washed ashore on the coasts of North Norway, and even on those of the Polar lands as far as the Gulf Stream reaches, but pumice-stone is not found at any elevation in Northern Norway, *but only at the lowest by the shore.* In fact, the highest line along which pumice-stone is found here *coincides nearly exactly with that of the travelled granite blocks in the neighbourhood of Tromsö.* In no case does it exceed the same.

KARL PETTERSEN

Tromsö Museum, Finmarken, Norway

A NEW FORM OF SPRING FOR ELECTRIC AND OTHER MEASURING INSTRUMENTS[1]

IN steam- and gas-engine indicators the pressure of the fluid on a piston produces a slight shortening of a spiral spring which is magnified by a lever, and so the pressure of the steam or gas is recorded. In what are usually known as spring balances there is also occasionally a magnification of the elongation of a spiral spring effected by the use of a rack and pinion. Such magnifying arrangements, however, not only introduce inaccuracy by the bad fitting of hinges or of teeth, an inaccuracy which

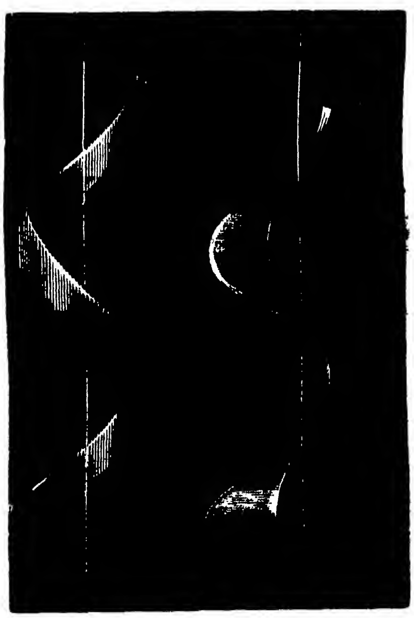

FIG. 1. FIG. 2.

is aggravated by wear, but they increase the cost of measuring-instruments and their liability to get out of order.

And, as an example of the difficulty of using the wheel and pinion for the magnification of an angular motion produced by a small force, the authors mentioned the fact that although they used this plan for a year or more in their electric measuring-

[1] Abstract of a paper read before the Royal Society by Profs. W. E. Ayrton, F.R.S., and John Perry, M.E.

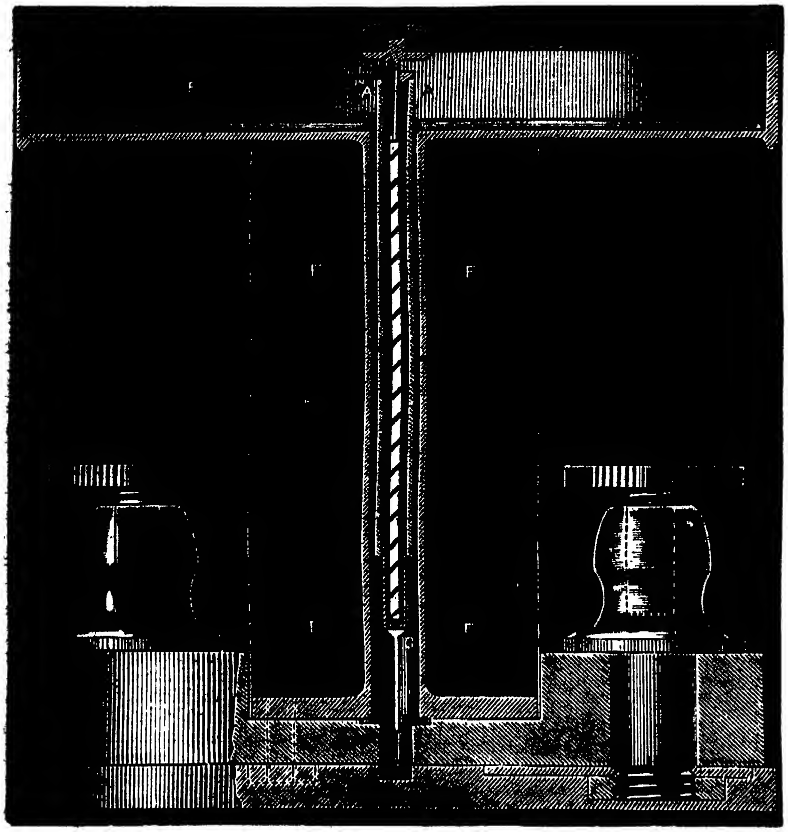

Fig. 3.

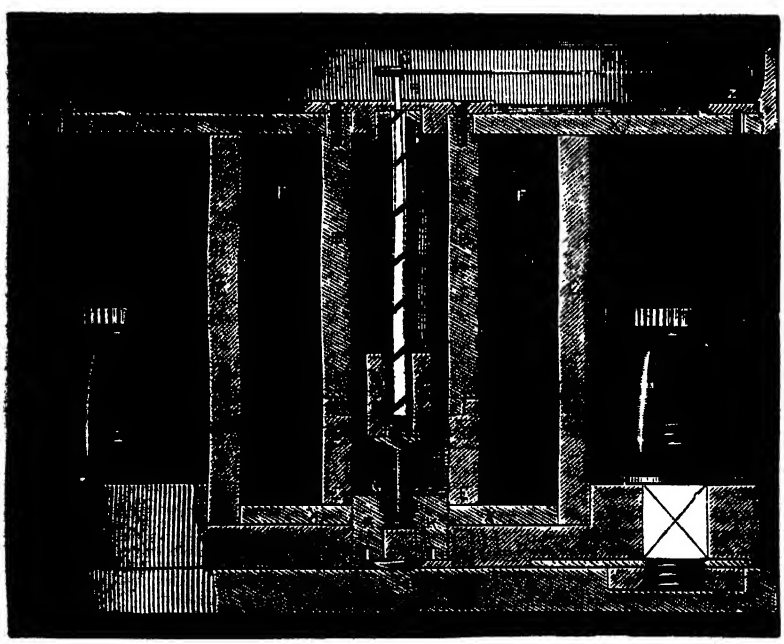

Fig. 4.

instruments, and although the wheels and pinions were made by a good watchmaker, still the friction involved in such a plan has induced them to abandon it in favour of the new arrangement which is the subject of their present communication.

The telescopic method employed by Weber, and the spot of light method due to Sir W. Thomson, for magnifying the effect of an angular motion are, of course, unequalled for stationary measuring-instruments, but for instruments which must be carried about and used quickly without the necessity of adjustment, these most ingenious reflecting methods are quite unsuitable.

With an ordinary cylindric spring, having a small angle between the osculating plane and a plane perpendicular to the axis, as is the case with all spiral springs such as are in practical use, it is well known that but very little rotation is produced between its ends by the application of an axial force. Consequently with such springs it is only possible to obtain magnification by the employment of a system of levers, or of a rack and pinion. It occurred to the authors, therefore, to consider whether it would not be possible to make a spiral spring of such a nature that for a comparatively small axial motion of its ends there should be considerable rotation of one end relatively to the other, and by the employment of which all levers, racks, and pinions could be dispensed with, so that no error could be introduced by wear and tear, or by want of fitting of joints, and further so that the temperature correction should be merely one affecting the rigidity of the material used as a spring, and not a correction such as had to be applied in consequence of the contractions and expansions of the various parts of an ordinary magnifying apparatus.

The theory of the strength and stiffness of the ordinary cylindric spiral spring of small angle was given for the first time in 1848 by Prof. James Thomson, andt he authors follow his method in investigating the laws governing the behaviour of spiral springs generally. They find that if the centres of all cross-sections of the wire, or strip, forming the spring lie on a right circular cylinder of radius r; if the spiral have everywhere an inclination a to the plane perpendicular to the axis of the cylinder, and if a force F act at one end of the spring along the axis, the other end of the spring being fixed; if B is the flexural rigidity of the wire in the osculating plane, and if A is the torsional rigidity about the spiral line at any place; if the angular motion, in a horizontal plane, of the free end of the spring relatively to the fixed end be called ϕ, and if the axial increase of length be called d, and the whole length of the spring along the spiral l, then—

$$\phi = l \mathrm{F} r \sin a \cos a \left(\frac{1}{\mathrm{A}} - \frac{1}{\mathrm{B}}\right) \quad . \quad . \quad (1),$$

and

$$d = l \mathrm{F} r^2 \left(\frac{\cos^2 a}{\mathrm{A}} + \frac{\sin^2 a}{\mathrm{B}}\right) \quad . \quad . \quad (2).$$

Assuming for the general investigation that the cross-section of the wire is elliptic, it is found that the rotation of the free end of a spring like Fig. 1 or Fig. 2 is greater the greater the inequality in the principal diameters of the elliptic section.

In Fig. 1 it is found that there is an uncoiling on the application of an axial pull. Fig. 2 shows a spring made of the same material, but the wire has been passed through rolls so as to flatten it in the opposite way, and now a rotation tending to coil it up is found to be produced by the application of an axial pull.

The twisting torque to which the spring is subjected is $F r \cos \alpha$, and the bending torque to $F r \sin \alpha$. But the twist must be multiplied by $\sin \alpha$, and the bend by $\cos \alpha$ when we project these motions on a horizontal plane. So far then as the total rotation in a horizontal plane of the free end of the spring relatively to the fixed end is concerned, it may be regarded as being produced by equal twisting and bending torques, each of them equal to $F r \sin \alpha \cos \alpha$; and the total rotation of the free end of the spring relatively to the fixed end, which is the special feature of the springs considered, is proportional to the difference between the two angular rotations produced in the wire by these equal bending and twisting torques. The twist alone would cause an increase in the number of coils, that is, a rotation in the direction of coiling which is the positive direction, while the bending, or rather the unbending, alone would cause a negative rotation, or one tending to uncoil the spring. When both occur together in the actual spiral spring subjected to an axial force, the total rotation is positive or negative, according as the angular twist or the angular bend is the greater. Hence the flexura and torsional rigidities of the wire alone determine whether the rotation is positive or negative.

It is well known, for example, that, when a wire of circular section is subjected to equal twisting and bending torques, the twist is greater than the bending for almost all substances, that is, substances in which the ratio of the modulus of rigidity to Young's modulus is between one-third and one-half. Hence we may expect that in a spring made of round wire, and with the spires making an angle of 45° with a plane perpendicular to the axis, the total rotation will be positive for an axial force applied so as to lengthen the spring. And experiment shows that this is the case.

If the wire be flattened and bent so that the flat side of the strip touches the cylinder on which the wire is coiled, as shown in Fig. 1, then the arrangement is such that the bending is greater than the twist. Hence an axial force applied so as to lengthen this spring causes a negative rotation, whereas if the strip be coiled as in Fig. 2, so that the edge of the strip lies against the cylinder on which it is coiled, an axial force similarly applied will now cause a positive rotation. It is almost certain that for any strip of material the positive value of ϕ obtained with the latter form of spring is likely to be greater than the corresponding negative value with the former kind, but the difficulty of manufacturing the second form of spring compelled the authors to confine their attention to the former type.

Having constructed some very delicate springs of the first kind, one of the first difficulties which the authors met with arose from the liability of such springs to acquire a permanent set, so that it became necessary to determine the dimensions of the spring which would give the largest amount of rotation with the minimum amount of stress in the material. Having made their calculation of the greatest amount of stress, the general conclusions arrived at are, that in order, with a given axial force, to obtain a large amount of turning of the free end of the spring, combined with small maximum total stress in the material, and not too much axial motion of the free end of the spring, the strip of elliptic section should be as long and as thin as possible, should be wound in a spiral such that the osculating plane makes an angle of 40° to 45° with a plane perpendicular to the axis of the spiral, and so that the smaller diameter of the elliptic section is at right angles to the axis of the spiral.

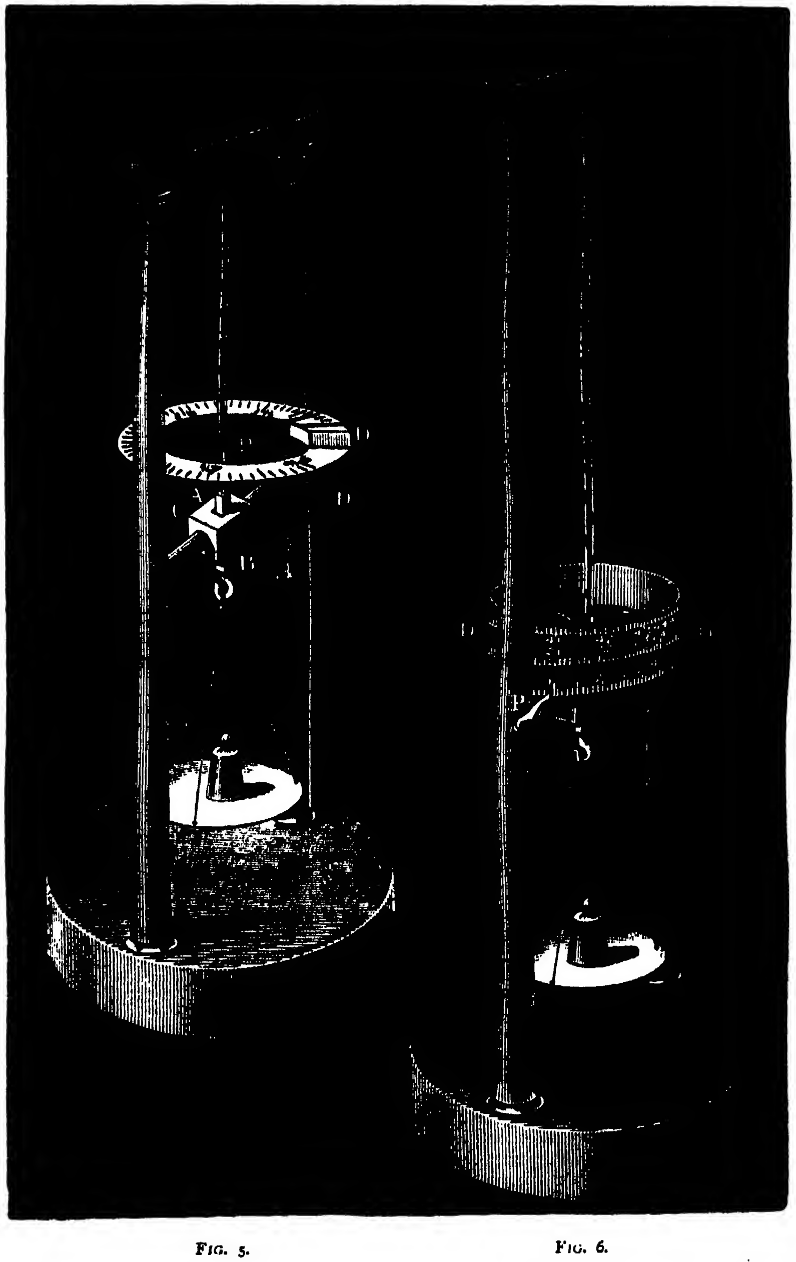

FIG. 5. FIG. 6.

In the springs employed by the authors in measuring-instruments the edges of the strip nearly touch one another in consecutive coils, so that the strip forms almost a continuous cylindric surface, the angle of the spiral being 45°, the cross-section of the strip being rectangular, and they find the following laws:—

$$\phi \propto \frac{lF}{b^3}\left(\frac{1}{4N} - \frac{1}{E}\right)$$

$$d \propto \frac{l F r}{b^3}\left(\frac{1}{4N} + \frac{1}{E}\right)$$

$$f \propto \frac{F}{b^2}$$

where f is the greatest stress in the material, b the thickness of the strip, N the modulus of rigidity, and E Young's modulus for the material.

The authors now show how their springs may be used to determine directly the ratio of the modulus of rigidity of a material to its Young's modulus, and they conclude their paper by describing some practical applications of their springs which they have already made in measuring-instruments. Thus by the employment of springs such as those described, they have succeeded in making *ammeters* and *voltmeters*, or instruments for measuring respectively electric currents and differences of potential, in which the pointer moves over in some cases as much as 270° of the scale instead of only 50°, which is all that can be obtained with ordinary galvanometers. One form of the instrument is shown in Fig. 3, where A A is a thin, hollow tube of charcoal iron attached at its lower end to a brass piece G guided at the bottom in the way shown. To G is attached the lower end of a spring made in the way described, of silver or hard phosphor-bronze, the upper end of which is attached rigidly by a thin rod to the glass top of the instrument, which itself is fastened rigidly to the framework of the instrument. The rod attached to the glass, and to which the upper end of the spring is attached, also serves as a guide to the top of the iron tube. In the space F F a solenoid wire or strip is wound, its ends being attached to the terminals shown. Hence, when a current is passed through the wire, the iron tube is sucked into the solenoid, and its lower end G, to which the spring is attached, receives a large rotatory motion, which is communicated directly to the pointer attached to the top of the iron tube. Parallax in taking readings of the pointer is avoided by the horizontal scale being on looking-glass in the well-known way.

By making the iron tube A A very thin, so that it is magnetically saturated for a comparatively weak current, by fixing it so that it projects into the solenoid a fixed distance which has been carefully determined by experiment, and by constructing the spring in conformity with the conditions worked out in this paper, so as to obtain a large rotation with minimum stress, and with not too much axial motion of the free end of the spring, they have succeeded in obtaining deflections up to 270° directly proportional to the current, and without any permanent set being given to the spring.

To prevent a spring taking a permanent set for a large deflection, it is of great importance that the spring after being delivered by the maker should receive a large degree of permanent set in the direction in which we wish it to be afterwards strained in ordinary working.

In spite of the fact that Prof. J. Thomson in the *Cambridge and Dublin Math. Journ.*, November 1848, explained the importance of initial strains in materials, the reason is not yet sufficiently well understood why when a round bar has been well twisted beyond the limit of permanent set in a certain direction it has twice as much elastic strength to resist torsion in this direction as in the opposite direction. Now in the very act of manufacturing these springs, that is in the bending of the strip, the material acquires strains which are just opposite in character to the initial strains which we wish it to possess, for, as already explained, if the spring be constructed as in Fig. 1, an extension of the spring produces a rotation tending to uncoil it. Hence a spring must not be regarded as ready for use until it receives a good set by means of a weight hung from its end.

This instrument is *direct reading*, the adjustment for sensibility being made by a small sliding coil, the correct position of which is initially determined experimentally by the makers, and in which position the coil is permanently fixed.

Theory of the Solenoid Spring Ammeter or Voltmeter.—If C is the current in amperes flowing through the coil, the attractive force on the iron core is

$$\frac{K C^2}{1 + S C},$$

where S is a constant, which is the greater as the current is smaller for which the iron tube A A, Fig. 3, becomes saturated with magnetism. The position of this iron core in the solenoid is so selected that K remains practically constant throughout the small range of downward motion of the core.

Since the rotation ϕ has been produced by an axial force, we know from the theory of the spring already given, that this axial force is $p\phi$, where p is some constant. Hence

$$p\phi = \frac{K C^2}{1 + S C},$$

and since S C is great in comparison with unity for such currents as we wish to measure, we have

$$\frac{p\phi}{K} = \frac{C}{S} - \frac{1}{S^2},$$

or

$$C = \frac{Sp}{K}\phi + \frac{1}{S},$$

that is, equal divisions of the scale correspond with equal additions to the strength of the current except close to the zero, and the authors do not usually graduate these instruments within 5° of the zero.

Shielded Measuring-Instruments.—When it is desired to use the instrument close to a dynamo machine or electromotor in action, they have adopted a different and somewhat special form of construction, which is shown in Fig. 4, by means of which the instrument is to a great extent shielded from even powerful external magnetic fields. In this instrument the electro-magnet consists of a hollow core, part of which, B B, is of charcoal iron, and part, D E, of brass, or other non-magnetic metal. The outside tube, C C, and the plates, X X, top and bottom, are also of charcoal iron. The space F F is filled with insulated wire or strip in electric connection with the terminal, so that when a current is sent through the instrument an intense magnetic field is formed between D and E, which are the poles of the electro magnet. To the iron tube A A, also made of charcoal iron, the spiral spring, in this case made of extremely thin hard steel, is attached, the other end being attached to the piece F, which is fixed relatively to the bobbin. The spindle G G, which is fixed to the moving iron core A A, moves freely in bearings H H, so that the only movements of which A is capable are one of rotation and one parallel to the axis of the bobbin. As the iron core A projects into the strong magnetic field between D and E, it is strongly attracted towards E when the current flows, and, as before, causes a large rotation of the pointer P over the scale. As a means of varying the power of the instrument an adjustable iron piece K is provided, which can be screwed nearer to or farther from the core A, and by the use of which the sensibility of the instrument can be adjusted so as to make the instrument "direct reading," that is to say, each division of the scale can be made to correspond with 1 ampere of current. or 1 volt difference of potential, and the employment of a constant such as 1·34 amperes, or volts, per degree, which has hitherto been necessary with our measuring-instruments, is now avoided. This power of adjustment produced by the use of the movable iron piece K, combined with the ease with which more or less wire can be wound on to the instrument, which also constitutes a second adjustment of sensibility, is of considerable importance, since the employment of a constant has not only led to error and delay in measurements made in electric-light factories, but has caused the breakage of the pointer or the destruction of an instrument from a far too powerful current being sent through it by an observer (often a man with little experience in the employment of instruments) having confounded the constant of some other instrument with that of the one he was using.

In the first of these magnifying spring ammeters and voltmeters made by the authors, the instrument did not show the *direction* of the current, but they have since added on the base of the instrument a small compass needle (not seen in the accompanying illustrations), which points out at which of the terminals the positive current enters, while the main pointer of the instrument shows as before the magnitude of the thing to be measured.

Weighing-Machines.—Another class of instruments in which they have practically employed this spring are weighing-machines, and Fig. 5 shows one of the arrangements adopted. The scale-pan is prevented from turning by the part A B being square and fitting very loosely a square hole in C. This arrangement introduces practically no friction, and prevents the moment of inertia of the scale-pan and load interfering, by means of a rotatory motion, with the rapidity with which the pointer comes to rest when a load is put into the pan. The position of the pointer P, which revolves when a weight is placed in the scale-pan, is read off upon the spiral scale D, which in the specimen shown was graduated in pounds. In another of these weighing-machines, shown in Fig. 6, the arrangement is the same with the exception that a cylindric scale D is fixed to the end of the

spring and turns with it; the pointer P fixed on the frame of the instrument points to an indication of the weight on a spiral line drawn on the cylinder D. This second arrangement allows of the employment of springs whose ends have a relative motion of five or six revolutions.

The authors also brought before the Royal Society a model showing a combination of bifilar and spiral spring suspension, in which great rotation and small axial lengthening or shortening are produced by an axial force.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Mr. A. E. Shipley, of Christ's College, will give a repetition of the Elementary Biology course in the Morphological Laboratory during the Long Vacation, beginning July 7.

The workshops of Mechanism will be open during the Long Vacation.

The Observatory Syndicate report 2305 observations of R.A. and N.P.D. in 1883-84, including 1579 observations of zone-stars made on 100 nights. The observations of standard stars are reduced to about the end of 1883. The zone-stars are completely reduced to end of 1881, the mean R.A. and N.P.D. to end of 1877.

It appears that the new expenditure entered into for professors, readers, University lecturers and demonstrators, and for apparatus and buildings, already exceeds the annual receipts from the colleges under the recent Act. Thus there is little chance at present of the appointment of the numerous readers contemplated by the University Commissioners.

The placing of a new story over the Mineralogical Museum for a laboratory of Elementary Biology has been sanctioned. The recommendations regarding a lecture-room and additions to the Physiological Laboratory are in abeyance.

The Botanic Garden Syndicate reports that during the past year the houses have been improved in many details. The Bromeliaceæ are now represented by fifty species. A new fern pit for filmy ferns is well stocked. The collection of Irises has been greatly improved, largely by Prof. Michael Foster's generous contribution, making it probably the finest in any botanic garden. The liberality of Mr. Barr has contributed a very fine collection of daffodils, and one of Funkias, not surpassed anywhere. Numerous plants of scientific interest have flowered in the Gardens and been figured. Col. T. Clarke has contributed a set of important Croci; Messrs. Low of Clapton a fine set of orchids.

The local lectures in provincial centres continue to gain large audiences, many courses of lectures on physical science and biology being given. Great difficulty, however, is felt in establishing sufficiently continuous courses of lectures in successive years, so as to give complete schemes of study.

The Cavendish and the Chemical Laboratories will be open during July and August.

Prof. Macalister will hold a class in Osteology during the Long Vacation. The Demonstrator will take a class in Practical Histology.

SCIENTIFIC SERIALS

THE *Journal of Botany* for May contains several articles of interest to cryptogamists:—Mr. W. B. Grove describes a number of fungi, some of them but little known or new; and the paper is illustrated by two plates.—Mr. S. Le M. Moore has paid special attention to the small class of endophytic algæ, and gives some interesting particulars regarding the structure and reproduction especially of *Chlorochytrium Lemnæ* and *Scotinosphæra paradoxa*.—Dr. Hance describes, under the name *Ptilopteris*, a new genus of polypodiaceous ferns; and Mr. J. G. Baker several new species of ferns in the collection of M. Humblot from Madagascar.—Among the minor notes evidence is given that *Centaurea Jacea*, L., must be regarded as a true British species.

In the number for June the only original article of importance is an exhaustive monograph by Mr. F. Townsend, of the variable species *Euphrasia officinalis*. He classifies the various forms under eight groups, only three of which are found in the British Islands.—A large portion of this number is occupied by the completion of the annual list (continued from the previous number) of new flowering plants published in periodicals in Britain during 1883. The length of this list affords evidence that the study of descriptive and systematic botany is not altogether neglected in this country.

Rendiconti del R. Istituto Lombardo, May 15.—Biographical notice of Giovanni Polli, with a list of his scientific productions, by Prof. Gaetano Strambio.—Influence of Virgil on the style of Dante, Petrarch, Metastasio, and Parini, by E. Giulio Carcano.—On the present condition of agricultural interests in Europe and North America, by Prof. Gaetano Cantoni.—On surfaces of the third order, by Prof. E. Bertini.—Experimental studies on the cure and prevention of tuberculosis, by Prof. G. Sormani.

Journal de Physique, April.—E. Blavier, study of earth-currents. In France these currents generally flow from north-west to south-west, and inversely; but often their direction changes and they go from north to south, north-east to south-west, east to west, or inversely. It is still impossible to give a general law.—E. Mascart, on the reciprocal action of two electrified spheres, shows that if the distance between centres is triple the diameter the law of Coulomb is correct to 2 per cent.—M. Brilloin, duration of swing of a magnetic system with its index.—M. Izarn, electro-dynamic and electro-magnetic experiments. An astatic float based upon that of Ampère is used to demonstrate the law of repulsion of consecutive elements of the current. The apparatus does not disprove Maxwell's view, however.—M. Buguet, action of two consecutive portions of one current.

May.—E. Mercadier, on the laws of transverse vibrations of elastic rods. From experiments on rods of steel and iron held at two points it appears that the number of vibrations is proportional to the thickness in the direction of the displacement, inversely proportional to the square of the length, and independent of the breadth.—P. Garbe, on Joule's law. Experiments made with an incandescent lamp placed in a calorimeter.—M. Marey, analysis of movements of photography. Gives a diagram of movements of a man running.—E. Mathieu, figures of liquid drops at the moment when they are about to detach themselves from a capillary tube fastened to the bottom of a vase.—M. Neyreneuf, on the transmission of sound.

Bulletin de l'Académie R. de Belgique, April 5.—Investigations on the spectra of the comets and on the luminous spectra of the hydrocarbonic gases, by Nicolas von Konkoly.—On the presence of the Biscay whale (Nordcaper) on the coasts of Norway in ancient and modern times, by G. A. Guldberg.—On the influence of temperature on the bands of the spectrum, by Ch. Fievez.—On the sand-heaps and sandstone boulders scattered over the Upper Devonian hills in the Sambre and Meuse districts, by Michel Mourlon.—On the influence of the atmospheric conditions on the appearance of certain colours in the scintillation of the stars; application of these observations to the prediction of changes of weather, by Ch. Montigny.—Spermatogenesis in *Ascaris megalocephala*, by Edouard Van Beneden.—On the advanced state of vegetation in Belgium in the month of March, 1884, by G. Dewalque.—Remarks on the cause of metamorphism in the rocks of the Recogne district, Luxemburg, by Jules Gosselet.—On the existence of a fourth species (*Balænoptera borealis*) of the genus Balænoptera in the North European waters, by G. A. Guldberg.

Journal of the Russian Chemical and Physical Society, vol. xvi. fasc. 3.—On the formation of amides of ammoniacal salts, by N. Menschutkin. The speed of amidation of the investigated acids increases with the increase of temperature, and the influence of temperature could be represented by similar curves for the different acids. The velocity of amidation depends also on the molecular weight, that of formic acid going on at a greater speed than those of acids which have higher molecular weights. Even with the aromatic acids the speed of amidation depends on the isomeric form of the acid. The results as to the dependency on isomerism and molecular weight are identical with those arrived at with regard to the compound ethers.—On the hydrates of the chloride of cobalt, and on the cause of the changes of colour of its dissolution, by A. Potilitzin.—On the action of the haloid salts of aluminium on the saturated hydrocarbons, by G. Gustavson. Organic bodies undergo great modifications when they enter into reactions with these salts, even when they enter into unstable temporary combinations; they acquire the capacity of entering into several new reactions, and undergo deep modifications even without being heated. The experiments might throw a new light on the part played by mineral salts in organisms, the component parts of which may be thus submitted to changes that are favourable for life.—On a new salt of rhodium, by Th. Wilm.—Note on M. Kanonnikoff's memoir on the refracting power of organic substances, by F.

Flavitsky.—On the preparation of animal colours from albuminoids, by W. Mihailoff.—Notes on the pseudosulphocyanogen, and on the dissolution of fibrine, by A. Lidoff.—On the thermal phenomena due to magnetism, by P. Bakhmetieff.—On the reproduction of curves traced by a point of the axis of a revolving body suspended at a point of its axis, by D. Bobyleff. The author publishes a photolithographed plate showing the different curves described by a conical pendulum revolving around its axis of symmetry, and balancing at the same time about its point of suspension. The apparatus having been improved, the curves are very symmetrical, and, notwithstanding the influence of the decrease of the oscillations, the curves are most like those deduced from the integration of the differential equations.—A preliminary note on the electrical properties of quartz, by G. Woulff.—On the conditions of sensibility of the method of Mance, a mathematical inquiry by D. Zolstareff.—On the changes produced in the intensity of an induction current by the introduction of a branch containing a bobbin, by J. Borgmann.—Notes on elementary optics, by P. Ziloff and M. Wolkoff.—Note on friction, by M. Kraiewitsch.

SOCIETIES AND ACADEMIES

London

Royal Society, June 19.—"On the Structure and Development of the Skull in the Mammalia. Part II. Edentata." By W. K. Parker, F.R.S.

My former paper on the structure and development of the mammalian skull was published in the *Philosophical Transactions* in 1874; it was on that of the Pig.

Since then, whilst gathering fresh and fresh mammalian materials, the greater part of my actual work has been on the skull of the other classes.

I have come to the conclusion that the Edentata are nearer of kin to the Monotremata than to the Marsupialia, and that if they did, as indeed they must have done, pass through a Metatherian, or Marsupial stage, they did not utilise it, but ran through it in an *abbreviated pre-natal* stage.

Of course the remarkable modification of their jaws, due to abortion, and in some cases complete suppression, of their teeth, is that which makes these forms so abnormal to the morphologist as well as to the zoologist.

As it happens, the most primitive form of Mammalia existing, the Prototheria (*Ornithorhynchus* and *Echidna*), are also abnormal on the same account, and thus the best standard existing by which to measure the height of the platform on which we find the Edentata is not itself normal, or straight, or perfect.

Now none of the Metatheria or Marsupials have suffered from this kind of degenerative specialisation; they therefore come in well as standards of measurement and comparison for the Insectivora next above them, but of little use here among the Edentata.

Prof. Flower, after working out the general anatomy of this group (*Proc. Zool. Soc.* 1882, pp. 358–367), has come to the conclusion that the Edentata of the Old World have little to do with those of the New.

That sounds like a hard saying to one not familiar with the structure of the group; it did to me, no long time ago, although what I had done at the group, long ago, went to prove the same thing; now, however, I am quite satisfied of the truth of my friend's deductions.

The Neotropical Edentata hold together much more than might have been expected; the Armadillos are the most isolated, but much as the Aard-Vark of the Cape looks like an archaic Armadillo without armour, he is not more than a very distant relative of the modern armed Armadillos.

Indeed, the curious coincidences that I have found between the structure of the Aard-Vark and that of a large Insectivore from a contiguous region, namely, the *Rhyncocyon* from Zanzibar, lead me to suspect that the Cape Anteater is an offshoot from the same stock, and is, indeed, the only Edentate that can be looked upon as probably arising originally from a Metatherian or Marsupial stock, like the Insectivora.

The other Palæotropical Edentata—the Pangolins—are perhaps still more isolated than the Aard-Vark, but they have not come so near extinction, and are found in more than one continent of the Old World.

If the term *Reptilian* might be applied to characters seen in any Placental Mammal, it might to what I find in this. This creature has most remarkable correspondences with the Reptilian group. Of course, the scaly covering is mimetic of the Lizard's scales, and is in reality made up of cemented hairs; that may pass; but not the structure of the sternum in some species, with its long "xiphisternal horns," as in the *Stellionidæ*, nor the cartilaginous abdominal ribs, as in the Chameleons and some other kinds. (See my memoir on the "Shoulder-girdle and Sternum," Ray. Soc., 1868, plate 22, fig. 13).

But the curious *ornithic* nasal bones, deeply cleft in front, the imperfect desmognathism of the palate, the feeble and segmented state of the anterior sphenoid, and the open pituitary space of the embryonic cartilaginous skull, all these things suggest that the Pangolins, whatever degenerative specialisation they may have undergone, never did rise to any height as Mammals.

Indeed, to me their *pre-natal* development—the Eutherian placentation—seems to be their best title to be ranked even amongst the low forms of the high Mammalia.

If a complete series of fossil types could be found, on one hand stretching backwards (or downwards) from the Glyptodons, and, on the other, from the Megatheroids, then, long before these two groups merged into a common Prototherian root-stock, we should find their differences one by one dying out.

Embryology would help us here very much if materials could be obtained. Even with the scanty treasures that I have been able to obtain, most remarkable things are shown.

Of the two Anteaters I have only been able to obtain the young (not the embryo) of the smallest and most aberrant type —*Cycloturus*—and of the Sloths only two embryos, and one of these considerably advanced, belonging to two genera, namely, *Cholœpus* and *Bradypus* (*Arctopithecus*, Gray).

But every step backward in the structure of the skull of the Sloth brings me nearer and nearer to what I see even in the young of the Little Anteater, and that it is possible for both of these types to have arisen from the same stock is no longer a doubtful thing.

But the skull of developing embryos of the Sloth (of either kind) forms a very valuable and easy-working key to what is difficult in the skulls of the extinct gigantic Megatheroids.

If this be the case, if Sloths, extinct or recent, have arisen during time from the same stock as the great terrestrial Antbear, and the little prehensile-tailed *Cycloturus*, then there is nothing in any other Order to shock the mind or to be a stumbling-block in the path of the most timid evolutionist.

That in the Armadillos the new husbandry, or growth, of hair—the correlate of milk glands—should thrive badly on the old stony ground of Reptilian horn-covered scales, breaking out where it can among the clefts, is not more wonderful than that this same new growth of hair in the Pangolin should mat itself together and imitate the scales of Reptiles and Fishes.

Physical Society, June 14.—Dr. Guthrie, president, in the chair.—New Member, Mr. Stanley Butler.—Mr. Hoffart read a paper on a new apparatus for colour synthesis, which he exhibited. The colours are obtained by sending through prisms the light from a series of platinum wires made incandescent by Grove or other cells. Three different rays can be compared or superposed at a time by the instrument shown. The rays are received into the eye through an adjustable eyepiece; and various ingenious devices are adopted in the construction of the apparatus. The intensities of the lights are regulated by rheostats in the circuits of the platinum electro-pyres. Lord Rayleigh, Mr. Stanley, and Prof. Perry commented on the apparatus, and Dr. Guthrie thought that it would be useful in studying colour-blindness.—Mr. Blaikley read a paper on the velocity of sound in small tubes—a continuation of experiments formerly brought before the Society by the author. Mr. Blaikley showed experimentally how his measurements were made. He found that pipes in which the upper proper tones were in harmonic order, or, better still, those in which they were far removed from the harmonic order, and therefore dissonant, were best for the purpose. He had obtained velocities from fine tubes varying from 11·4 to 88·2 mm. in diameter, the former giving 324·38, and the latter 330·13 m. per second as the velocity of sound. In free air Mr. Blaikley thought the velocity would come out 331 m. per second. The differences of velocity for the different pipes were very regular. Lord Rayleigh, Dr. Stone, and Dr. Guthrie made some observations on the paper, Dr. Stone remarking that the diameter of a pipe modified the pitch of the same rate, a fact noticed in musical instruments. In experiments on water-waves Dr. Guthrie had found that in rectangular troughs the rate of oscillation was less than in circular ones.—Mr. Howard read a paper by himself and Mr. Hayward, on the thermal relation-

ship between water and certain salts, such as sulpho-ethylate. &c. Curves of results were given and interpreted.

Royal Meteorological Society, June 18.—Mr. R. H. Scott, F.R.S., president, in the chair.—Dr. Benjamin A. Gould, Director of the Cordova Observatory, Argentine Republic, was elected an Honorary Member.—The following papers were read:—The equinoctial gales—do they occur in the British Isles?, by Mr. R. H. Scott, F.R.S. The period investigated was the fourteen years 1870-84, and only those storms were selected which had attained force 9 of the Beaufort scale at more than two stations. The results show that the storms are all but exclusively confined to the winter half-year; and also how, for a certain interval, the stream of storm depressions sets over the British Isles, and then for a time takes another path, leaving this country at rest. In some years there are as many as four or five storms in a fortnight, and in others there are none, or only one. It is further shown that there is no strongly marked maximum at either equinox.—On the physical significance of concave and convex barographic or thermographic traces, by the Hon. R. Abercromby, F.R.Met.Soc. The author shows that a falling barogram is convex when the rate of the fall is increasing, concave when decreasing; and conversely, that a rising barogram is convex when the rate is decreasing, concave when increasing. As the rate of barometric change is proportional to the steepness of the gradients which are passing, and the wind also depends on the gradients, the author suggests the following rules for judging the coming force of a gale from the inspection of a barogram:—A convex barogram is always bad with a falling barometer, and good with a rising one; and a concave trace is sometimes a good sign with a falling barometer, and not always a bad indication with a rising one. The convexity or concavity of a thermogram is likewise shown to depend on the rate of thermal change. A method is given by which the distribution of diurnal isothermals over the globe can be deduced from the diurnal thermograms in different latitudes, and it is shown that the shape of diurnal isotherms on a Mercator chart for a limited number of degrees of latitude is similar to the shape of the curve of diurnal temperature range, if we turn time into longitude, and temperature into latitude, on a suitable scale.—Maritime losses and casualties for 1883 considered in connection with the weather, by Mr. C. Harding, F.R.Met.Soc. —The helm wind, by the Rev. J. Brunskill, F.R.Met.Soc. This is an account of a wind peculiar to the Crossfell Range; and its presence is indicated by a belt of clouds, denominated the "helm barr," which settles like a helmet over the top of the mountain.—Climate of the Delta of Egypt in 1798 to 1802 during the French and British campaigns, by Surgeon-Major W. T. Black, F.R.Met.Soc. The author has collected and discussed the meteorological observations made in Egypt during the French and British campaigns at the beginning of the present century.

Geological Society, May 28.—Prof. T. G. Bonney, D.Sc., F.R.S., president, in the chair.—John George Goodchild, Alexander Johnstone, and John Taylor were elected Fellows, and Prof. G. Meneghini, of Pisa, a Foreign Member of the Society. —The following communications were read:—The Archæan and Lower Palæozoic rocks of Anglesey, by Dr. C. Callaway, F.G.S., with an appendix on some rock-specimens, by Prof. T. G. Bonney, F.R.S. The object of the author was to furnish additional proof of the Archæan age of the altered rocks of the island. He held that the Pebidian mass on the north was fringed by Palæozoic conglomerates containing, amongst other materials, large rounded masses of limestone, derived from the calcareous series on the north coast, these conglomerates being probably a repetition by reflexed folding of those which lie at the base of the Palæozoic series. In like manner conglomerates which margined the western (Holyhead) schistose area contained angular pieces of altered slate undistinguishable from some of the Pebidian rocks of the north-west. These conglomerates dipped to the east, forming the western side of a syncline. Near Llanfihangel were sections which showed not only the Archæan age of the gneissic and slaty (Pebidian) groups, but also the higher antiquity of the former. These conclusions were derived from the occurrence of granitoid pebbles in the slaty series, and from the presence of masses of the slate, as well as gneissic fragments, in the basement Palæozoic conglomerates. The author was at present unable to accept the Cambrian age of the Lower Palæozoic rocks, and considered that the fossils he exhibited tended to confirm the views of the Survey on the correlation of those strata. The paper concluded with a sketch of the physical geography as it probably existed in Ordovician times. An appendix furnished by Prof. Bonney tended, by microscopic evidence, to confirm the proof furnished by the paper.—On the new railway-cutting at Guildford, by Lieut.-Col. H. H. Godwin-Austen, F.R.S., and W. Whitaker, F.G.S. In this paper the authors described a section exposed in a new railway-cutting just north of Guildford station. The beds exposed are chalk and Eocene strata at the base, with overlying Pleistocene or drift-beds. The Eocene beds appear at each end of the cutting, the London Clay resting upon Woolwich and Reading beds as described in 1850 by Prof. Prestwich; and the interest of the section is due in part to this exposure of the Woolwich and Reading beds, which are rarely seen in this neighbourhood, and in part to the thick mass of Pleistocene clays and gravels overlying the lower Tertiary deposits. The authors pointed out that the most interesting questions connected with these high-level gravels and sands of the ancient Wey are as follows:—1. What was their relation to the topography of the country in the past? 2. What relation do they bear to the outlines of the country at the present day? 3. What is their age? They showed that when the gravels and sands were deposited the main drainage of the country was the same as it now is, though the river was sixty feet above its present level. The sands with mammalian bones were probably an accumulation in a re-entering bend of the river, similar to one now existing a little further north. The river appears at first to have been more rapid, when the lower ironstone gravels were deposited; then slower, when the sands accumulated. Some change of levels ensued, and a considerable portion of the deposits was removed before the upper strata of loam and flints were formed. It is probable that the gorge of the Wey was no longer an outlet to the north whilst these beds were being deposited. In general the loam and flint beds are horizontal, whilst in some localities they are displaced in a manner remarkably like what is seen in the Glacial deposits of Alpine valleys. They contain land shells in places. The land surface indicated by the lower gravels and sands at Guildford is of older date than that described by Mr. R. A. C. Godwin-Austen in the country to the southward, and especially in the valley of the Tillingbourne. The deposits near Guildford belonging to the two epochs were noticed in some detail. Both are pre-Glacial, and have been formed when the climate was temperate. The overlying Glacial deposits formed of chalk-detritus, flints, and loam are attributed to the action of land ice, and the probable effects of a low temperature are described and illustrated by those observed on the plateaus around Chang Cheumo in Tibet.—On the fructification of *Zeilleria* (*Sphenopteris*) *delicatula*, Sternb., sp., with remarks on *Ursatopteris* (*Sphenopteris*) *tenella*, Brongn., sp., and *Hymenophyllites* (*Sphenopteris*) *quadridactylites*, Gutb., sp., by R. Padé.—Description of a new and effective process of soldering aluminium and using aluminium in the soldering of other metals, by M. Bourbouze.—Account of a simple process for purifying arseniferous zinc, by M. L. L'Hote.—Note on the nervous system of *Hyalinœcia tubicola*, Mull., *Eunice torquata*, Quatr., *Lumbriconereis impatiens*, Clap., and other members of the Eunice family, by M. G. Pruvot.—Researches on antiseptic substances and the consequences resulting from their use in surgical practice, by M. B. Ratimoff.—Remarks accompanying the presentation of M. Capellini's work on "The Upper Chalk and Priboma Group in the Northern Apennines," by M. Hébert.

BERLIN

Physiological Society, May 16.—Prof. Waldeyer read a communication from Mr. Hoggan of London, on an investigation upon the nerve-endings in the skin of the Polar bear. The results of this investigation have already been published in English. The preparations which had been sent over by Mr. Hoggan were exhibited in the demonstration-hall of the Institution.—Herr Schmey gave a short account of an investigation upon the alterations in the sense of touch which supervene in the skin after certain treatment. After having by several weeks' practice fixed a determinate constant for his "sensation-circles" (*i.e.* for the territories on his skin which corresponded to a unit of sensation), he made experiments upon himself to determine the influence of the fatigue of an extremity upon the sensibility of the skin, further, as to the effects of the application of a mustard sinapism, of a hyperæmia produced by nitrite of amyl, and again of pressure on the nerve supplying the particular portion of skin experimented upon. He found among other things that in the first stage of skin irritation by a sinapism the sensibility of the skin was increased, in the second stage it was diminished, and that pressure upon the ulnar nerve was followed by a lessened sensibility in the area of its distribution.—Prof. Kronecker described the experiments made by Dr. Markwald to determine accurately the effects of *Secale cornutum* and its various constituents,—the physiological effects of the following preparations in particular, which are known in commerce and have been introduced into practical medicine, were the subject of investigation; these were Extractum Secalis cornuti, Ergotin from various sources, Ergotinin, and Sclerotinic acid. All the physiological actions, those upon the uterus as well as those upon the regularity of the heart-beat, upon the blood-pressure, and the hæmostatic effects were investigated, in some cases individually, in others collectively, on dogs and rabbits. The Extractum Secalis cornuti first raised the blood-pressure, which afterwards sank to below the normal, and afterwards gradually rose again to the normal height or to a little above it. The presumption that a complex preparation caused the mixed action was verified in subsequent experiments. For the ergotin produced in different degrees, according to the purity and goodness of the preparation, a more or less marked increase of the blood-pressure, which was followed by a sinking to the normal level; whereas sclerotinic acid always produced a fall of the blood-pressure, followed by a rise to the normal pressure. The pulse showed slowings after the exhibition of ergotin, interrupted by successions of accelerated pulsations, giving rise to the impression that this drug elicited a periodic stimulation of the vagus. This phenomenon did not occur after section of the vagi, and was peculiar to this preparation. Satisfactory evidence of the existence of hæmostatic properties in ergotin could not be obtained, though these were present in an eminent degree in sclerotinic acid; the amount of blood that flowed out of a cut artery in a unit of time after the exhibition of ergotin actually increased to an insignificant extent, whereas it decreased very considerably after exhibition of sclerotinic acid. Upon the contraction of the uterus the preparations secale extract, ergotin, and sclerotinic acid have alike a decided effect, but ergotinin, which occurs in commerce in the form of a solution, was in this respect, as well as in the other respects previously investigated, sometimes inoperative and at other times uncertain. Rules for the therapeutical use of the preparations can easily be deduced from the physiological actions above described, but it is to be remarked that sclerotinic acid is very painful as a subcutaneous injection. This is not the case with a solution of ergotin. The results of the investigations were illustrated by Prof. Kronecker by means of numerous diagrams of curves.

VIENNA

Imperial Academy of Sciences, May 23.—L. Karpelles, on gall-mites (Phytoptus, Dug.).—L. Doederlein, contributions to a knowledge of the Japanese fishes.—R. Wegscheider, on isobutyl-naphthalene.—E. Spiegler, on an acetamine of the fat-series of high molecular constitution.

May 29.—Anniversary Meeting.—The meeting was opened in presence of the Crown Prince Rudolf by the Curator of the Academy, Archduke Rainer.—The Reports of the past year were read by the General Secretary, Prof. Siegel, and the Secretary of the Mathematical and Natural Science Class, Prof. Stefan.—Obituary Notes were read by the Secretaries on the members deceased—Prof. T. W. Gintl (Prague), Sir Edward Sabine, Jean Baptiste Dumas, Joachim Barrande, Julius Schmidt (Athens), Adolphe Wurtz.—The Reports were also read on the work done by the Prehistoric Commission and the Central Institute of Meteorology by Prof. Stefan. It was stated in this Report that the meteorological stations increased in number during 1883, ten stations being added during this year, and that a registering anemometer had been set up on the summit of the Obir Mountain (2147 m.), which works regularly.—Prof. Emil Weyr of Vienna University gave an address on the geometry of the ancient Egyptians, dealing with the contents of the papyrus, Rhind.

CHOLERA AT TOULON

THE doubt which existed as to whether the outbreak in and about Toulon was true cholera or only the sporadic type of the disease must be regarded as set at rest; indeed, from the date when the details of the outbreak first became public, it is probable that those who declared the affection to be only of a local and sporadic character were mainly influenced by political motives. Dr. Fauvel apparently now stands alone in the determination not to admit that the epidemic is the same as that which is known as Asiatic in type, and the fact that the source of the infection cannot by any chance be attributed to England is almost enough of itself to mould the views of this able physician. The onset of the disease, the sudden outbursts during its subsequent course, its diffusion to other towns and places, and notably to Marseilles, and the fatality attending it, all prove that we have not to do with the disease which in this country goes by the name of English cholera, and which when occurring in hotter climates and under favouring conditions of filth is known as sporadic, but with true cholera, such as was imported into the south of France and into England from Alexandria in 1865 and 1866.

Of the future course of the epidemic it is at this stage almost impossible to speak with any authority, but it is very certain that occasional lulls in the number of attacks —occurrences which are immediately reported as indicating a subsidence in the outbreak—cannot be regarded as having much significance in this respect; for it is one of the essential characteristics of cholera, especially in the early stage of an epidemic, to exhibit periodic fluctuations both in the number and in the intensity of attacks. So, also, the hold which cholera acquires in any town or district is largely dependent on the sanitary circumstances of the locality, and it is well known that in Toulon the conditions of filth which so especially favour the spread of that disease are exceptional in point of general prevalence and intensity. Marseilles stands much higher in this respect, but French towns which are regarded as ranking among the most advanced in so far as their sanitary circumstances are concerned stand but low in the scale when compared with the healthy towns of England.

Another circumstance has rendered it well-nigh impossible to foretell events, and that is the flight of panic-stricken persons to all parts of the country. Instead of dealing with the outbreak in its early stage, the French authorities made a secret of the matter, and by the time that the Government which takes precedence of all others in extolling the virtues of *cordons sanitaires* were prepared to act, they found that their secret had oozed out, and that thousands had fled beyond all *cordons;* and so once again the fear of restrictive measures such as quarantine and its allied practices has defeated the very objects which the advocates of that system so unhesitatingly claim for them.

Bringing the lesson of the epidemic home to ourselves, it must be admitted that, with the constant communication which exists between the various French and English ports, we are not free from the risk of having cholera imported. To prevent importation by imposing a lengthened quarantine on the almost numberless vessels arriving in England from the various French ports would be an impossibility; and our Government, fortified by the decision of the last European Conference held at Vienna, will unquestionably trust, as heretofore, to a combined system of inspection and isolation. For this purpose all the Orders and Regulations which were re-issued during the prevalence of cholera in Egypt last autumn remain in force, as also does the special provision that persons removed to the hospitals of the Metropolitan Asylums Board are not to be regarded as having become pauperised in consequence of such removal. At our various ports vessels arriving from infected places will be inspected, first by the Customs Officers, and then by the Sanitary Officers of the ports; all cases of cholera or choleraic diarrhœa will be at once removed to such hospitals as have been provided for the purpose; any doubtful cases will be detained to undergo a short supervision; the healthy will be allowed to land; and no detention of the ship or of persons on board will exceed forty-eight hours, a period regarded as ample in view of the short period of incubation in the case of cholera.

Last year, when the question of the importation of cholera from Egypt was so urgent, the Local Government Board issued a special Memorandum to port, urban, and rural sanitary authorities, urging them to observe the utmost cleanliness in relation to all sources whence any pollution of water drunk or of air breathed could possibly emanate, and a vast amount of valuable sanitary work was carried out with the object of preserving water-sources from contamination, of excluding sewer and drain air from dwellings, and procuring the rapid and regular removal of all sources of nuisance and offensiveness from premises. We shall this year profit from so much of that work as was of a permanent character; but since it is essentially on cleanliness of all our surroundings that we must rely, the work of 1883 should be continued and renewed this year. Such work is never wasted. Even should cholera die out in the south of France, and never come nearer to us than it has done already, progress in sanitary work will be amply remunerative in the prevention of those diseases which, in point of origin, so much resemble cholera, and it will, in addition, tend to the moral and social improvement of those who only cling to filthy surroundings because the means of cleanliness have never been provided for them.

We are glad to learn that Dr. Koch, the chief of the recent German Cholera Commission to Egypt and India, has left Berlin for Toulon. His journey is undertaken partly at the wish of the French Government, who are anxious to know more of the methods of investigating and suppressing cholera which that gentleman has pursued with such signal success. Dr. Koch is going to France alone, although he had full permission to take with him any of his recent colleagues in Egypt and India. Moreover, the German Imperial Cholera Commission has concluded its deliberations. The result has now been submitted to the Government, and will be immediately published. The Commission holds that the sanitary condition of Germany in general is not favourable

to the outbreak of the epidemic. Further to lessen the danger, every separate household is to be requested immediately to carry out scrupulously the precautions and orders in reference to disinfection which are to be issued by the Government.

THE EARTH AS A GLOBE

Die Erde als Weltkörper, ihre Atmosphäre und Hydrosphäre, Astronomische Geographie, Meteorologie und Oceanographie. Von Dr. Julius Hann. Pp. 209. (Prag: F. Tempsky; Berlin: G. Freytag. 1884.)

IT sometimes happens that the leading words in the title of a book give a very inadequate impression of its contents. Such, to an English reader at least, might be the case as regards the work before us. We should have rather anticipated a discussion of the relation of our globe to the surrounding universe, or at any rate its position as a member of the great family dependent on the same central source of light and warmth. A compatriot of the writer, it is but fair to suppose, would have formed a juster anticipation of what the title-page expresses and the contents explain, that we have here a description of the earth as an isolated globe. The first section sets before us its form, dimensions, density, seasons, magnetism in its several aspects, and auroral illumination. The following one discusses the various conditions of our atmosphere with regard to temperature, pressure, humidity, rainfall, winds, cyclones, and all that English people express by the brief and usually not complimentary phrase, "the weather." The third section relates to the "hydrosphere," or fluid envelope, comprising its extent, colour, saltness, temperature, currents, waves, and tides. This programme is carried out not only with a great deal of industry, and care, and judgment, but with a clearness and facility of expression which are not always remarkable in scientific treatises. We are very favourably impressed by it as a whole, and look upon it as a very valuable addition to the branch of science which it undertakes to elucidate. At the same time there are a few respects in which improvement might be desirable. We should have preferred, for instance, some explanation of the comparative imperfection of the longitude-measures obtained from Jupiter's satellites, as well as from lunar distances; the aëronautic details might have borne expansion with advantage; and we are a little disappointed in the very scanty notice of atmospheric electricity. Of this it may indeed be said that its investigation is peculiarly difficult, and that many of its modifications hitherto defy explanation; but it would have been, we venture to think, a preferable course, especially as so much pains have been taken with magnetism, if more explicit reference had been made to an influence of so powerful, yet so occult and mystèrious a nature.

We may add, though we are treading on uncertain ground, that our author's descriptions of the English climate, or rather of what he considers that it ought to be, with regard to dryness or the reverse, are not altogether in agreement with our own experience. The character of our month of February, as expressed in the very ancient and still surviving epithet, "fill-dyke" (or "fill-ditch"), or in an old rhyme of the seventeenth century—

> "Foul weather is no news, hail, rain, and snow
> Are now expected and esteem'd no woe,"—

does not tally well with our author's estimate of January as the most rainy of months, at least in West England; and his description of October as having a full maximum of rain in East and a secondary maximum in West England matches as little with the traditional remark of half a century ago, that eighteen fine days always occur in that month. Nor again is the April of West England, as he asserts, characterised by dryness, which used to be predicated of March, together with, in our grandsires' remembrance, a degree of heat which caused the unyoking of the weary ox during the noontide hours; so that we find in these instances the anticipation or postponement of a month. Our ground however is, as we have said, somewhat insecure; and we are obliged to admit that our old-world remembrances are often as far out of keeping with our present experience as the theoretical deductions of Dr. Hann. The October of late years has certainly not maintained its reputation for fineness, and we miss the regularity as well as the intensity of the equinoctial gales. There is an element of uncertainty and instability not only in the daily or monthly condition of the weather but in its annual recurrence, at least as far as our own climate is concerned; and it has presumably a much wider extent: a similar remark is not unknown in Switzerland, and was confirmed as to North Italy by the disappointing experience of that most accurate astronomer, Baron Dembowski, who in his latter years had, as he informed the writer of these lines, to contend with an unwonted amount of unfavourable skies. Such variations may possibly be very slowly periodical, and, if so, their recurrence might well be the subject of a careful examination. The weather-lore of modern days is undoubtedly far in advance of the imperfect forecasts of a century ago, and the pages before us have done well in aid of its further progress; but experience shows that the science of meteorology requires to be set upon a deeper and stronger foundation. The neglect of one or more imperfectly appreciated factors is probably indicated by the uncertainty or inconsistency of the results. One such factor may readily be pointed out in electrical agency, latent on every side, but awakened from time to time in manifestations equally fearful and incomprehensible. How to take due account of this all-pervading influence is a problem for future generations.

In closing our brief notice of this valuable work we would especially allude to the especial clearness—with few exceptions—of the very satisfactory as well as numerous diagrams which illustrate it. So far as we have observed, the faults of the book are very few: the greatest, as far as English students are concerned, is one that may easily be rectified, and we trust soon will be—its appearance in a foreign tongue.

PRACTICAL BOTANY

Das botanische Practicum. Von Dr. Eduard Strasburger. (Jena: Gustav Fischer, 1884.)

THE production of a series of important works in rapid succession has pointed out Prof. Strasburger as one of the most prominent figures among botanists of the present century. It will be readily

seen from the character of his researches, which deal for the most part with questions of minute structure and development, that he combines unusual power of close observation with originality of treatment and wide knowledge of methods. These qualities, together with a clear style of exposition, are those most needful for the production of a handbook for the guidance of students in the botanical laboratory; and the result does not disappoint the expectations of those who have been awaiting the appearance of Prof. Strasburger's volume.

The 600 pages of which the book consists are printed partly in large, partly in small, type, the former being intended for the beginner, the latter for the use of more advanced students. The whole is divided into thirty-four lessons, corresponding to the number of practical demonstrations habitually given in the course of one semester in a German University. But, as the author freely admits in his preface, it is not assumed that a detailed study of the objects named in one lesson could be made in the time during which one demonstration lasts; it is, however, stated that the time would usually suffice to give the student a general idea of the most important points. With due deference to Prof. Strasburger, in this admission lies the weak point in the book; if such a system as this be adopted with students on their first entrance into the botanical laboratory, and if the work be so presented to them that it should appear to them desirable rather to hurry through the study of a number of objects than to pay closer attention to a few, the result would naturally be the encouragement of a superficial style of observation; this method is not at all consistent with that usually adopted by German professors, and our experience as teachers on this side of the Channel does not lead us to approve of it. If, however, the student be not limited in respect of time, he would by carefully and successfully working through the course, both of large and small type, laid down for him, find himself at the end of it an accomplished laboratory botanist, well fitted to strike out a line of research for himself.

After giving a short introductory description of the microscope itself, and a list of makers and prices, Prof. Strasburger leads the student on by gradual steps, from the observation of starch-grains and their reactions, to the more complete study of the cell, with its included bodies, special attention being paid to the plastids and their various modifications. Having thus become acquainted with the general morphology of the cell, he is introduced to the study of tissues, the epidermis with its appendages being taken first, and subsequently the vascular bundles and surrounding tissues, as seen successively in the axis, root, and leaf; the constituent elements of these several tissues in the mature condition are made the subject of detailed observation. It is to be remarked, however, that little attention is paid to the comparative study of the *course* of the vascular bundles in the shoot, and the methods of its investigation; it is true that on pp. 282-303 this subject is dealt with in small type, but even there the treatment is almost entirely confined to the modifications of arrangement at the point of transition from stem to root; thus the student who works through the large type only will gain a very complete knowledge of the details of structure of the vascular bundle in various types of plants, while his knowledge of the [illegible] of the whole bundle-systems in those plants may be very limited.

This course of study of the tissues of the vascular plants in the mature condition having occupied eighteen chapters, the 19th and 20th are devoted to a comparative investigation of the structure of growing points of stems and roots, and the development of tissues, while later chapters deal successively with the structure of the vegetative organs of the Mosses and of various forms among the Thallophytes. In Chapters XXIV.-XXXII. Prof. Strasburger treads upon ground which is peculiarly his own, and brings before the student in succession various examples illustrating the reproductive processes in plants, starting from the lower forms, and proceeding to those of higher organisation. In the concluding chapter he illustrates the processes of nuclear- and cell-division by means of examples already familiar to those who have followed his brilliant researches in this quarter.

The whole book thus forms a compendious and, including the small type, a very complete course of instruction for the student in the botanical laboratory. Throughout the text ample information is given as to methods of treatment, and the use of reagents; and this information is drawn together and made accessible by means of a special index (No. III.). Of the other indices, which form a most valuable addition to the work, the first refers to the names of the plants investigated, and the second to the instruments used, while, finally, No. IV. is a general index to names, reagents, and apparatus.

Prof. Strasburger has treated the question as to the advisability of placing drawings of the objects under investigation before the student in the laboratory in a truly characteristic manner. He has illustrated his book by 182 woodcuts, all of which have been specially prepared for this work. Whatever may be our views as to the effect of the use of such figures on the student, these, being drawn in Prof. Strasburger's well-known style, constitute in themselves a most welcome addition to the figures hitherto published.

There can be no doubt that among senior students and teachers this book will be appreciated as its great merits deserve; and that it will henceforward be an indispensable item in the furniture of the botanical laboratory. But, as may be gathered from what has been said above, it is no book for the cramming student; time must be allowed, and even more time than its author seems to realise, if full advantage is to be reaped from the course laid down. For this reason it is to be feared that it will not be so popular among our junior students as with those who are in a position to judge better of its value. F. O. B.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Chalk and the "Origin and Distribution of Deep-Sea Deposits"

IN a letter of Mr. Starkie Gardner's in the last number of NATURE (p. 192), he stated that my opinion as to the Chalk

having been a shallow-water deposit was "based exclusively on the present habits of the very few genera of Mollusca that have survived from the Chalk period, and seems quite in contradiction to the far more important groups, the Sponges, Echinodermata, and the minute organisms of which the formation is so largely compo ed, while no opinion has yet found its way into the hands of geologists regarding the depth of water indicated by the Crustacea and the fishes of the Chalk." Mr. Gardner appears to have overlooked that passage in my Address to the Biological Section of the British Association (to which he refers in his letter), wh rein I added, "Mr. Woodward tells me that the Chalk Crustacea are shall w-water forms." Dr. Woodward is certainly no mean authority on fossil Crustacea. As to the surviving genera of Chalk Mollusca being "very few" in number, I would refer him and my readers to the long list of genera given in my Address, which was furnished by our great palæontologist, Mr. Etheridge, and to the exclusively littoral habits of some of those genera. And with respect to the Sponges, Echinodermata, and minute organisms being "far more important groups" than the Mollusca, I must leave that question to naturalists in general. Sponges (silicious as well as horny or ceratose), and Echinoderms are notoriously not restricted to deep water. Quite the contrary. They live at every depth from the shore between tide-marks to the abyssal and benthal zones. The "minute organisms" which enter so largely into the composition of the Chalk, for the most part, if not entirely, inhabit the surface of the sea. J. GWYN JEFFREYS

Protoplasmic Continuity in Plants

IN the very interesting article on "The Continuity of the Protoplasm through the walls of Vegetable Cells," which appeared in NATURE of June 19 (p. 182), reference is made to the doubt which still exists as to "whether the continuity is maintained from the earliest stages, or is established later." This point is so important in its physiological bearings, as the article goes on to show, that I may, perhaps, be allowed to state that, with regard to one group of plants, the question appears to be already settled. I allude to the Red Sea-weeds or the *Florideæ*. The writer of the article makes no mention of these plants, but, as I have described elsewhere (see *British Association Report*, 1883, p. 547, and *Journal of Botany*, February and March 1884), many of them exhibit a very notable system of intercellular connections, which, extending over the whole thallus, renders the protoplasm practically continuous from the base of the frond to the extremities of its furthest ramifications. Now in these cases the continuity is certainly maintained from the first, and is due to the mode of cell division by which the thallus is built up. Into the details of this there is no need to enter further than to say that, when the protoplasmic body of a cell divides into two or more portions, these d not become completely separated from one another, but remain connected *inter se* by strands of protoplasmic material, which grow in thickness with the growth of the cells, and thus maintain the continuity from the earliest stages onward. So far, then, as concerns the *Florideæ*, I venture to think the physiological import of the phenomena of continuity may be safely discussed on the assumption of its existence *ab initio*. What that import may be I do not propose to consider, my object being simply to point to the *Florideæ* as throwing valuable light on the whole subject, and giving some support to the view that "the entire plant or organ is practically one whole—one mass of protoplasm cut up into chambers which communicate with one another, and bounded by a membrane on the exterior." THOMAS HICK

Aseismatic Tables for Mitigating Earthquake Shocks

WITH respect to Mr. C. A. Stevenson's letter in your last issue (p. 193), I may state that my information was obtained from Mr. R. H. Brunton's paper on "The Japan Lights" in *Proc. Inst. Civ. Eng.*, vol. xlvii., pp. 6-8, 35, and from the communication by Messrs. Stevenson in the "Discussion" on that paper (pp. 26-29). The results referred to by Mr. Stevenson have, perhaps, been obtai ed since this paper was read (November 14, 1876). W. TOPLEY

28, Jermyn Street, London, June 27

Black Rain

A REMARKABLE shower of black rain fell here and in the neighbourhood last Sunday, the 22nd inst. The forenoon had been fine, though somewhat hazy, but about 3.30 p.m. heavy cumuli formed to north and north-west. Gradually a dense mass of cloud and haze came from the northward, presenting a lurid, threatening aspect, and it become so dark that one could not read a book indoors. At 4.30 rain began to fall, at first a few drops, and soon after a heavy downpour. When this commenced I noticed a number of black objects floating in the air, which I at first took to be flies or winged ants, but they rapidly increased in number, and on looking at them more closely I found them to be particles of soot, on an average about the size of the common fly. Their number was so great that, it appeared for ten minutes to be snowing black, the descent of the blacks being slow, like that of snowflakes. After it had rained heavily for fifteen minutes, these "blacks" ceased and the air became lighter, but the rain continued for another hour, and altogether I measured ·30 inches in my gauge. I find on inquiry that this black rain was noticed in the whole neighbourhood—at least four miles to the north-east and two miles to westward, hence it cannot have been due to local chimneys. As far as I can ascertain, the shower was entirely local; it seems to have followed a narrow course from north to south only a few miles wide, and did not extend to either Eastbourne or Hastings.

Fletching, Sussex, June 24 W. J. TREUTLER

A Cannibal Snake

RATHER a strange occurrence came recently before my notice, and thinking perhaps you might care to insert it in your columns, I send you the facts of the circumstance. A few days since, towards evening, I killed a snake just close behind my house; it measured about a yard and a half in length, was one of the most deadly of the numerous kinds of snakes found in Java, and bears the name of "Oelar belang." On examining it later I found what I thought to be the tail of another small snake protruding from its mouth, but on pulling it out I was greatly surprised to discover that it was really a snake of the same species, and of almost the same length. There was certainly not more than three inches' difference in the length of the two snakes, and at the time I killed the outside snake only about an inch and a half or two inches of the tail of the one he had swallowed protruded from his mouth. The outside snake was of course considerably the thicker of the two, but this may be attributed to his having swollen after, or rather during, his tremendous meal. The natives here say that the two snakes must have been fighting, the victor afterwards swallowing his opponent. I should be pleased to know whether such an instance has ever before been brought before your notice, or whether it is really an uncommon case. EDWIN H. EVANS

Soemedang, Java, May 20

Peronospora infestans

ON the 22nd inst. I observed that this fungus had appeared on the haulm of the potato crop in one or two places in my garden in this city. On examining to-day a potato crop in another garden a mile distant from mine, I perceived that that crop was likewise affected. Considering the dryness of the spring weather, the appearance of the disease is remarkable. According to my observation, the attack of the mould is a month earlier than usual. It may be added that hereabouts, this season, blight of all kinds is prevalent, while last year was blight free. Inclosed is a specimen of diseased haulm. J. LL. BOZWARD

Worcester, June 24

KEPHIR

IN No. 10 of the *Journal of the Berlin Chemical Society* for June 23 is a communication on this substance by M. Struve of Tiflis, continued from a previous note in the same journal of February 25.

Kephir is a form of fermented milk which has been prepared and in use amongst the inhabitants of the Northern Caucasus for a great length of time, and occupies with them a similar position as an article of diet and medicine to that of kumis in the south-eastern steppes of Russia.

Kumis was first brought into notice in 1784, and has since then been pretty fully investigated and taken a definite position, but kephir has only been generally

known even in Russia for about two years, although several notices of its medicinal properties have been contributed to the Caucasian Medical Society. The knowledge and spreading use of this new drink in Russia dates apparently from an investigation and paper read on this new ferment product by E. Kern at the Moscow meeting of the Imperial Naturalists' Society in 1881.

Kephir is prepared by fermenting milk, either sheep's, goats', or cows' milk, with what are termed kephir-grains, the process taking place in leather bottles (*Burdinks*). These grains are the ferment proper, the leather bottle not being supposed to be absolutely necessary. During the fermentation the milk becomes very much changed, and at the same time there is a reproduction of the ferment substance or kephir-grains, which is removed after a certain stage of fermentation has been reached, and after drying in the sun may be preserved, and serves again to effect the fermentation process. Nothing is known of the origin of this peculiar ferment. An analysis of the grains dried at 100° C. gave:—

Water	11·21
Fats	3·99
Soluble peptone substances	10·98
Proteids soluble in ammonia	10·32
,, ,, potash	30·39
Insoluble	33·11

The insoluble residue exhibited under the microscope an intimate mixture of yeast-cells, and the *Bacterium dispora caucasica* with a few Leptothrix and *Oidium lactis* possibly as accidental. This 33·11 per cent. of insoluble matter seems to be the only active part of the kephir grains. On preparing some kephir in bottles with this, the product became slightly effervescent after twenty-four hours, and contained a small amount of alcohol. After three days the amount of alcohol and carbonic acid was much increased. On making an examination of the fermented liquid after one, two, and three days respectively, the quantity of casein found was practically the same in each case. But on treating the casein so obtained with dilute ammonia and then dilute potash solution, in no case was there a complete solution. An amount of insoluble residue was obtained from the *third-day* experiment of ·22 per cent. of the casein, and which consisted entirely of yeast-cells. From this is concluded that the fermentation of the milk is entirely due to *Saccharomyces mycoderma*, the *Bacterium dispora caucasica* not taking any part in the fermentation, and this seems to be further supported by the fact that the "finished" drinkable kephir will start fermentation in fresh milk in the same manner as the kephir-grains.

The *Bacterium* "*dispora*" which Kern noticed, and to the action of which he ascribed the peculiar properties of kephir, probably results, in quite a secondary manner, from the employment by the people in the Caucasus of the old leather of the bottles in which kephir has been fermented. In this process in leather bottles the yeast-cells are in contact with the leather, and to some extent possibly grow or extend into it, so that they become modified physically, and the rapidity of fermentation is much lessened. Any animal tissue which has become, as it were, saturated or penetrated by yeast-cells is capable of causing sugar solutions and also milk to ferment, and can therefore be used in place of these kephir-grains for the preparation of kephir.

HENRY WATTS, F.R.S.

We regret to announce the death of Mr. Henry Watts, F.R.S., the well-known chemist; he died on June 30, of syncope from failure of the heart's action, after a very short illness.

Henry Watts was born in London on January 20, 1815. He was educated first at a private school in London, and subsequently attended lectures at the University College, London. In 1841 he graduated as Bachelor of Arts in the University of London. In 1846 he entered the Birkbeck Laboratory of Chemistry, then recently established at University College, as assistant to his highly valued friend, the late Prof. Fownes, and in that capacity was engaged in directing the work of the students till the death of Prof. Fownes in 1849, and afterwards till 1857 under Prof. Williamson. In 1848 he was engaged by the Cavendish Society to prepare a translation, with additions, of the great "Handbuch der Chemie" of Leopold Gmelin, a work which extended to eighteen volumes, and occupied a large portion of his time for more than twenty years, the last volume and the index having been published in 1872.

In 1858 he began to prepare a new edition of "Ure's Dictionary of Chemistry and Mineralogy"; but finding that this book, the last edition of which appeared in 1831, had fallen too much behind the existing state of chemistry to be made the groundwork of a dictionary adapted to the requirements of the time, he undertook, with the consent of the publishers, and the assistance of a staff of contributors distinguished for their attainments in different branches of physics and chemistry, the compilation of a new "Dictionary of Chemistry and the Allied Branches of other Sciences." This work, in five large octavo volumes, was completed in 1868; but as additions were required to keep it abreast of the continual advances of science, a supplementary volume was published in 1872, a second supplement in 1875, and a third (in two parts) in 1879 and 1881.

Mr. Watts brought out three editions of "Fownes's Manual of Chemistry," viz. the tenth, published in 1868, the eleventh in 1872, and the twelfth in 1877, and also part 1 of a thirteenth, in 1883.

He held for many years the appointments of editor of the *Journal*, and librarian, to the Chemical Society, having been appointed to the former in 1850, and to the latter in 1861. He was elected a Fellow of the Chemical Society in 1847, a Fellow of the Royal Society in 1866, and a member of the Physical Society in 1879. He was also an Honorary Member of the Pharmaceutical Society, and a Life Governor of University College.

He was engaged at the time of his death in writing a new and abridged edition of the "Dictionary of Chemistry"; he was also editing, in conjunction with Mr. C. E. Groves, a re-issue of "Knapp's Technology," and the thirteenth edition of "Fownes's Manual of Chemistry," of which the second volume is left in manuscript.

GEOLOGY AT THE BRITISH ASSOCIATION

The arrangements for the Geological Section of the British Association are now well advanced, and some idea may be formed of the amount of work likely to be done. Several meetings of the Organising Committee have been held in London, at some of which Principal Dawson has been present. From the list of members of the Association to whom vouchers for the meeting have been issued we learn that English geology will be represented at Montreal by six professors—those of Edinburgh; Trinity College, Dublin; University College, London; Victoria University, Manchester; and University College, Nottingham; and by Prof. T. R. Jones. The Geological Society sends sixty of its Fellows, including the President, Secretary, and six other Members of Council. Many of the leading geologists of Canada also are Fellows of that Society. The Geological Survey sends six of its members, and six or more who have at one time been on the staff.

The President of the Section is Mr. W. T. Blanford, Secretary of the Geological Society, who will afterwards represent that Society at the Philadelphia meeting of the American Association; the Vice-Presidents are Prof. T.

R. Jones and Mr. A. R. Selwyn; the Secretaries are Dr. G. M. Dawson, Messrs. F. Adams, W. Topley (Recorder), and W. Whitaker.

The International Geological Congress meets at Berlin in September, and this will prevent many Continental geologists from going to Montreal; Dr. Richthofen, however, will probably be present, and will communicate a paper on some comparisons between the geology of China and North America. It is hoped that others may also arrange to come.

Meeting in the typical Laurentian country, it is only to be expected that the Archæan rocks will receive much attention. Amongst the papers sent or promised are the following:—Prof. Bonney, on the Lithological Characters of the Archæan Rocks in Canada and Elsewhere; Mr. Frank Adams, on the Occurrence of the Norwegian "Apatitbringer" in Canada, with a few Notes on the Microscopic Characters of some Laurentian Amphibolites; Dr. T. Sterry Hunt, on the Eozoic Rocks of North America.

On Palæozoic Geology and Palæontology generally the following are expected:—L. W. Baily, on the Acadian Basin in American Geology; E. W. Claypole, the Oldest Known Vertebrates—an Account of some Fossils recently discovered in the Silurian Rocks of Pennsylvania; Mr. J. H. Panton, of Winnipeg, Geological Gleanings from the Outcrops of Silurian Strata in the Red River Valley, Manitoba.

Principal Dawson will give a Comparison of the Palæozoic Floras of North America and Europe, whilst Mr. J. S. Gardner will deal with the same subject as regards the Cretaceo-Tertiary Floras.

Other papers are:—G. F. Matthews, on the Geological Age of the Acadian Fauna, and on the Primitive Conocoryphean; E. Wethered, the Structure of English and American Coals.

After the Azoic and Palæozoic rocks of Canada, the Drift Deposits are of great interest. The following papers bear on this subject:—Mr. A. R. Selwyn, on a Theory of Ice Action in the Formation of Lake Basins and in the Distribution of Boulders in Northern Latitudes; the Rev. E. Hill, on Theories of Glaciation; F. Drew, on the Thickness of Ice in the Himalayan Valleys during the Glacial Period.

Amongst other papers of interest are:—Prof. Hull, on the Geology of Palestine, giving an account of his recent explorations; Prof. T. R. Jones, on the Geology of South Africa; W. Whitaker, on the Economic Value of Geological Maps, with especial reference to water-supply, illustrated by the Survey Maps of the Chalk area in England.

Papers are also promised by Mr. Arch. Geikie, Dr. G. M. Dawson, Prof. V. Ball, Prof. W. Boyd Dawkins, Dr. C. Le Neve Foster, W. Carruthers, H. Bauerman, E. Gilpin of Halifax, N.S., and others.

Other papers will be sent by American and Canadian geologists, particulars of which have not yet been received. Prof. James D. Dana and Dr. James Hall, if not present in person, will probably send one or more communications.

Several Reports will be submitted by Committees, or by persons appointed for this purpose at the last meeting of the Association (the name mentioned is that of the Secretary to the Committee, or the Reporter):—Prof. J. Milne, Earthquakes in Japan; W. Cash, Fossil Plants of Halifax; G. R. Vine, British Fossil Polyzoa; Dr. H. W. Crosskey, Erratic Blocks of England, Wales, and Ireland; Prof. T. R. Jones, Fossil Phyllopoda of the Palæozoic Rocks; C. E. De Rance, Underground Waters; J. W. Davis, Raygill Fissure, Yorkshire; C. E. De Rance and W. Topley, Erosion of Sea-Coasts of England and Wales; F. Drew and Prof. A. H. Green, the Present State of Knowledge respecting the Interior of the Earth; W. Whitaker, Geological Record; W. Topley, National Geological Surveys; and Progress of the International Geological Map of Europe.

With several sections of the Association the work is mainly confined to the meeting room. Geologists are more fortunate, their most pleasant memories of these meetings are with the hills, rocks, and streams of the district. At and near Montreal there is much to be seen. Mount Royal rises steeply behind the city, a mass of eruptive rock intruded through the Silurian beds. From the summit a grand view is obtained over the Laurentian Mountain on the north, and over the hills and rolling plains of Silurian rocks on the south and east. From amongst these latter rise the more sharply defined trap hills of Montarville, Beloil, and Rougemont. The excursions are of especial geological interest. Niagara is only a short run of 300 miles away; the Rocky Mountains will be reached by a special train over the Canadian and Pacific Railway.

The Local Committee at Montreal is preparing a guide-book to the city and neighbourhood, which will contain a geological map. A general Geological Guide to the Dominion will be prepared by the Geological Survey of Canada.

PRIMARY EDUCATION AT THE HEALTH EXHIBITION

THE recent opening of the City and Guilds of London Institute by the Prince of Wales, and the simultaneous issue of a special catalogue of the educational exhibits at the Health Exhibition, which are for the most part housed in that Institute, has been the means of drawing much public attention to this most interesting and valuable collection, and renders some account of it opportune. It is probably not too much to say that no such elaborate and extensive collection of educational appliances, methods, and results, has ever been brought together before, notwithstanding the fact that, the primary object of the whole Exhibition being to elucidate the conditions of health, it was considered expedient to attach to the principal display mainly such objects and appliances as had a special relation to healthful school life. This limitation, however, has been interpreted somewhat liberally, and the result is a collection in which can be studied and compared the educational systems in primary, general, and technical education as practised in the British Islands, France, and Belgium, and to a less extent in Germany, Sweden, Switzerland, the United States, and Canada. It is earnestly to be hoped that such an opportunity for comparing their own systems, practice, and results with those of others, whether English or foreign, will not be allowed to pass by our schoolmasters and schoolmistresses, as well as by members of School Boards, and indeed by all interested in this vast subject. We hear with pleasure that it is intended to organise visits there by parties of London masters and mistresses, and we hope that arrangements will be made enabling provincial educationalists to avail themselves of the advantages offered by this temporary display at South Kensington, which will not be prolonged beyond the middle of October.

Two foreign Governments, those of France and Belgium, have organised elaborate collective exhibitions, showing the methods and results both of primary and secondary education in those countries, and the catalogue of the French exhibit is prefaced by ten closely printed pages containing an admirable summary of the present position of education in France, which has of late made most rapid advances. The money which neither the Liberals of the Restoration, nor those of the Monarchy of July, nor the *Corps Législatif* of the Second Empire, had been able or willing to find for popular education, the Parliament of the Third Republic, definitely consolidated in 1877, has not feared to demand of the State, notwithstanding the pressure of taxes resulting from the foreign

and civil war of 1870. In 1882-83 there were 5,432,151 pupils, and 129,657 public teachers (of whom only 21,781 were uncertificated) in the elementary primary schools of France, and the general outlay of the State for primary education amounted in the same year to 94,881, 942 francs, or about 3,825,000*l*.

While cordially recognising the very great trouble that the Ministers of Public Instruction in France and Belgium have taken to illustrate their respective systems, we must not forget that our Education Department occupies a different and wholly unique position, and hence that the English Government, as a Government, is unable to make a similar display. Our Education Department scrupulously abstains from enforcing particular methods and processes, simply requiring that by some local means, voluntary or otherwise, efficient schools shall be provided, and it then confines itself to the estimation of results and to the distribution of funds provided by Parliament in aid of the local efforts; in a word, its control is indirect rather than authoritative. The intelligent foreigner therefore has to search through the collective exhibits of the great voluntary societies which have so long and so largely influenced English primary education, and also of several of the municipal bodies called into existence by the Education Act of 1870, in order to become conversant with the methods and results of English schools. In the special catalogue for education, each of these bodies which exhibits has taken the opportunity to place on record an account of its aims and history, and of the scope and character of its present work. Such additions to this catalogue, occupying many closely printed pages, render it a very admirable hand-book to the whole subject of education, and add immensely to its value. Among the most interesting and valuable statements of this kind are those issued by (to use the shorter titles) the National Society, the British and Foreign School Society, the Wesleyan Education Committee, the Sunday School and the Ragged School Unions, and the School Boards of London, Birmingham, Glasgow, and Edinburgh.

There is one Society, however, which merits more than a passing notice, since its collective exhibit is not merely one of the most remarkable and interesting in the whole Educational Exhibition, but is also one from which a great deal is to be learnt. It is cosmopolitan in its aims, and exhibits the results of its schools in Belgium, France, England, the United States, Canada, Egypt, and India, although its head-quarters are in Paris. The Institute of the Brothers of the Christian Schools was founded in 1680 by the Venerable Dr. J. B. De La Salle, who was the first to establish primary education in France, and also training colleges for teachers. At present the Institute has nearly 12,000 Brothers, distributed over thirteen countries, directing 1200 schools, with an attendance of about 330,000 pupils, who, we regret to say, are all boys, the Brothers not concerning themselves in any way with the education of girls. The Brothers everywhere follow the same general methods of teaching, while they modify the details according to the custom of the country in which they are, varying their programmes also to meet local requirements and the wants of the times; for example, in their United States schools, where all the boys stay till about sixteen, every boy in the first class learns (1) shorthand writing, (2) the use of the type-writer, (3) the Morse alphabet, since without these acquirements the Brothers are unable to get situations for their pupils. The rooms in the Technical Institute, as well as the space in the Belgian and French Courts devoted to the results of their work, will well repay very careful examination, since only their most leading features can be here indicated. Foremost among these, and bearing distinctly upon a subject recently discussed both in this journal and in the *Spectator*, is their system of models, maps, and atlases for the scientific teaching of geography, which are exhibited by Brother Alexis. These maps were the first hypsometrical maps published in French, and, we believe the first of the kind published anywhere for school use, and are intended to give, by a suitable arrangement of colours, clear notions of the real configuration of the earth's surface. An introduction to their study is afforded by a glass tank, with a very uneven bottom, upon which contour lines are marked; when this is filled to various depths with water, the effects of changes in the relative level of land and sea are clearly and effectively demonstrated. This demonstrative or objective method is the keynote to the system of instruction adopted by the Brothers, and its effect is seen in many instances, notably in the splendid school museums of Annecy (Savoy), Beauvais, Rome, and Marseilles, in which the specimens are all collected by the pupils, and classified by the masters; in the apparatus employed in scientific and handiwork teaching; and in their system of teaching drawing, the results of which, as illustrated by an enormous series of designs, entirely the work of pupils, are almost incredible. The lithographed notes of science lessons distributed to the pupils, and the extensive series of science and other text-books, written in various languages by the Brothers, all deserve close inspection.

The Ministry of Public Instruction in Brussels illustrates most fully the Belgian educational methods, and here again one of the most prominent points is the teaching of geography, which is most completely systematised and thoroughly scientific; the minutely detailed maps of the War Department form the basis of much of this, dealing thoroughly with the physical and geological conditions of the country, which are gradually shown, one thing at a time, in a progressive series of maps. The technological and other school museums (notably that at Verviers) collected by the pupils, deserve special notice, as does the whole apparatus for handicraft teaching, such, for example, as the pasteboard models made by the pupils for the demonstration of problems in solid geometry, and of algebraical formulæ treated geometrically. The city of Antwerp furnishes a very interesting collective exhibit, further illustrating these points, and in this connection may also be mentioned the single exhibitors, D. Windels, whose zoological models of animals to scale are admirable, and J. B. Gochet, who shows a complete course of geography.

In the French Section the method and good gradation of all the school work and the way in which these points are illustrated in the exhibit are very remarkable. Here again we find great prominence given to the objective method of teaching in almost every subject; the results of the handicraft teaching of children from ten to thirteen in the Département du Nord are almost incredibly good, while the method of it in the Prevot Orphanage is excellent. The excellent choice of books for school libraries, the system of instruction in rhetoric and in the duties of citizenship, the results of the École Normale de Travail Manuel, and the programme of instruction for 1882, are particularly noticeable.

Of the English system, as illustrated by the Societies and the School Boards, the exigencies of space allow us to say but little. The publications of several of those enumerated above are well known, as are also their school appliances. For the methods and results of school work, the exhibits of the School Boards must be consulted. Here we are at once struck with the comparative absence of the apparatus for, and the results of, that objective system of teaching which stands out so prominently in the Continental systems. A praiseworthy exception to this, however, is to be found in the room devoted to the Birmingham School Board, where Mr. Jerome Harrison exhibits the apparatus and results of the itinerant system of teaching science to every child above Standard IV. in the Board schools of that town. The systematic arrangement of every subject of instruction, and especially of the needle-work, is particularly notice-

able here. More space is occupied by the London School Board, whose lending libraries for schools and reference libraries for pupil teachers are well selected. The geographical teaching cannot, of course, be compared with that on the Continent, though some of the district maps are good. Fair provision is made for teaching science to pupil teachers, but there is a lamentable deficiency in the apparatus for this and for the whole system of object-lessons, when the needs of the scholars themselves are considered. The School Boards of Edinburgh and Glasgow show some excellent models, photographs, and plans of school buildings of the newest type, and some remarkable specimens of drawing. The Wesleyan Education Committee show some excellent results of the scientific and handicraft training of boys, and some very simple yet remarkably effective appliances for elementary geographical instruction.

Although these collective displays by public bodies are the most interesting feature of this portion of the Exhibition, there is much that will repay examination in the various objects shown by many single exhibitors of the great variety of school desks and furniture; some of the desks of G. M. Hammer, G. E. Hawes, and H. Simon and Co., deserve more than a passing notice, as do also the revolving partitions of Hodkinson and Clarke. Among maps and charts the collection of Mr. E. Stanford stands out prominently, and is specially noticeable for the five series of physical and orographical maps, some of which in frames are on continuous sheets and rollers. Mr. Bacon's maps are singularly clear and good for school use, and his picture-lessons in geography are a step in the right direction. The apparatus for teaching music, exhibited by J. Curwen and Sons, is perhaps not approached by any similar exhibit. The science charts and diagrams produced by M. Emile Deyrolle are of an extremely high degree of excellence, and deserve to be made widely known. The educational publications of such firms as Messrs. Cassell and Co., Messrs. Gill and Sons, the Messrs. Johnston, Messrs. Griffith and Farran, Messrs. Bemrose and Sons, and Messrs. William Collins, Sons, and Co., who are all well represented, are too well known to need more than a reference.

In a second article we hope to deal in a similar way with the exhibits of apparatus and results of scientific and technical teaching carried to a higher degree than in mere primary schools, and also, briefly and by way of introduction, with that range of subjects which may be shortly described as comprising the technical education of children and girls. It may perhaps be permitted to the writer to say, as the result of a very close examination (extending over more than a week continuously) of the exhibits relating to primary education in various countries, that one important lesson to be learnt from the comparison of Continental methods with our own is the great advantage afforded by the objective system of teaching, and by the adoption of that systematic order and method in all subjects of instruction, literary or otherwise, to which the name scientific, in the highest and best sense of the term, is applicable.

WM. LANT CARPENTER

WORK-MEASURING MACHINES[1]

UNDER this title a little *brochure* has recently appeared from the pen of the Rev. F. J. Smith, B.A., of Taunton, in which work-measuring dynamometers, or *ergometers*, as the author terms them, of various forms are described. Amongst these machines there are many devised by the author himself, and some of these are of considerable interest and much originality. The transmission ergometers of the type originally invented by General Morin deserve notice in particular. The following is the general principle involved in transmission ergometers:—

Let it be supposed that a belt passes over from the driving wheel of a prime-mover such as a steam-engine to the pulley of a dynamo which is being driven. One half of the belt is subjected to a strong pull, the other is relatively slack. Then if we could introduce spring balances into the two parts of the belt, and if we could read the difference of the tensions T and T′, and if we multiplied this T − T′, expressed in pounds, by the velocity of the belt in feet per second, we should then have the "foot-pounds per second" spent in driving the dynamo. From this we can calculate the horse-power by dividing it by 550, since 550 foot-pounds per second is one horse-power. This we may write algebraically:—

$$\text{H.P.} = \frac{(\text{T} - \text{T}')}{550} v;$$

where v denotes the velocity of the belt in feet per second.

Now since such an arrangement as this cannot be easily carried out, the usual method is to place between the engine and the dynamo some instrument capable of showing the tension of the belt in pounds, and the velocity of the belt, and in certain cases these instruments can even give a continuous record of the work done. The ergometer devised by Mr. Smith is an admirable instance of such a combination, and it undoubtedly possesses points of superiority over all transmission dynamometers hitherto invented. A view of the machine (see figure) shows how the ergometer is arranged. The central shaft, of Whitworth steel, which is tubular at each end and link-shaped between, carries two pulleys. One is keyed to the shaft and carries two bevel-wheels, these engage with another bevel-wheel which forms part of the second pulley, which is loose on the shaft.

To each of the two bevel-wheels, as shown in the diagram, there is fitted a cylindrical drum, on these either gut or steel tape is coiled over three-fourths of their faces, and the gut or tape is attached to a cross-head. The latter is in turn attached to a cylindrical steel spring placed within the link, and from the cross-head a rod of steel, passing through one end of the link, actuates the pointer of a dial, whereby the pull on the spring attached to the end of the link is shown. This instrument resembles therefore the earlier dynamometer of Morin in having two pulleys; the angular advance of one of them being regulated by a spring. But in Morin's form the spring was simply an extended piece of steel. In the more recent modification by Profs. Ayrton and Perry, coiled steel springs are also used; but in that instrument the springs are liable to fly out by centrifugal force, and the arrangement for observing the angular advance is an optical one, requiring an observation of a silvered bead by a reading-telescope. In Mr. Smith's ergometer there is no such tendency of the spring to fly, and the tension is read direct on a dial. The speed indicator is shown just below. If a continuous record of work is required, the steel rod is either attached to a recording drum or to an integrating apparatus.

The instrument having been placed between a prime mover and a machine to be tested, the belt from the prime-mover drives the loose pulley, and another belt from the fixed pulley drives the machine to be tested. The tension on the driving side of the belt causes the spring to be extended by means of the bevel-wheels, and difference of the tensions is indicated by the pointer of the dial. The instrument is calibrated by hanging known weights from strong thin cords or catgut strings passing round the pulleys, and marking the dial in accordance with the weights.

The springs used by Mr. Smith are made by Messrs. Salter and Co., they are of four sizes, capable of being extended 2 inches by 50, 100, 150, and 200 lbs. respectively. They have been put to severe tests, but have some

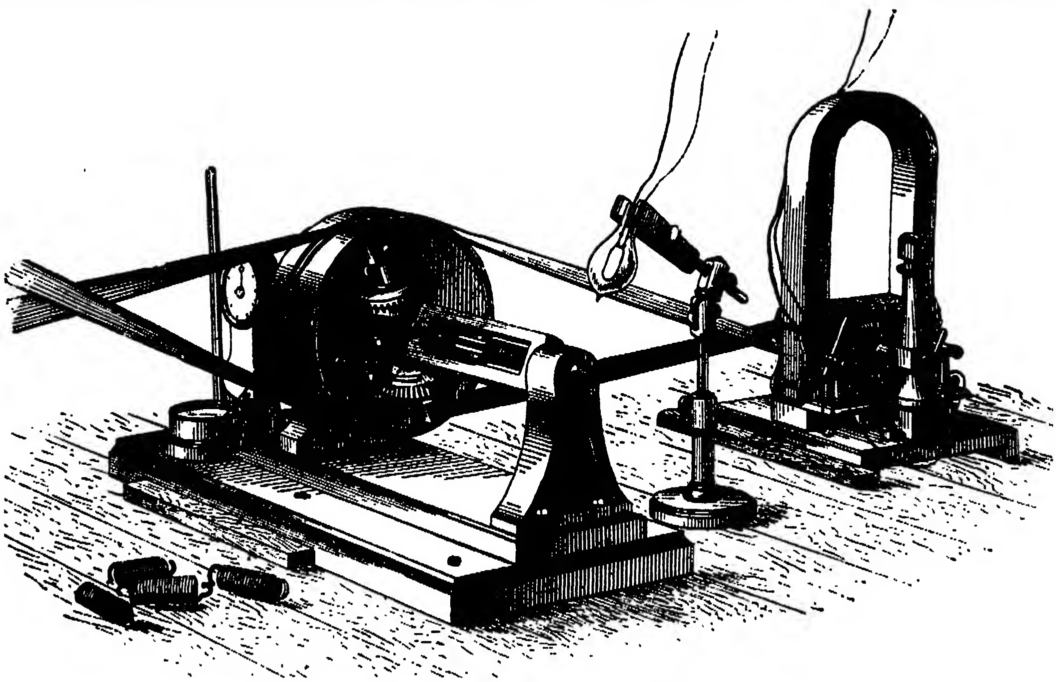
[1] "Work-Measuring Machines." By Frederick J. Smith, B.A. 32 pp. 12mo. (London: E. and F. N. Spon. 1884.)

out of them quite unaltered. However, so as to leave no doubt as to the accuracy of the readings of the ergometer, the instrument is finally calibrated by another method, which is new; it is as follows:—

Let a prime-mover (a water-wheel appears to be the most steady) drive the transmission ergometer, and let the ergometer drive a pulley on a shaft embraced by a suitable friction ergometer, such as a Prony brake or an Appold's brake, and let the work done against friction be calculated. This should agree with the results of the transmission machine. If it does, we may conclude that it has been correctly calibrated. The advantage of this method is that the transmission machine is tested while running in its usual condition. When testing a dynamo care should be taken that the speed indicator be well attached to the shaft the velocity of which it is measuring. A piece of coiled spring, such as is used in a dentist's lathe, answers well to connect it to the machine.

The leading feature of this instrument is the position of the spring in it. The axis of the spring and of the shaft coincide; the result of this is that it is hardly at all affected by centrifugal force. When springs of slight pull are used and the ergometer is driven at a great velocity, the deformation is considerable, and would introduce considerable error into the result.

The deformation of the spring has been fully appre-



Smith's Transmission Ergometer.

ciated by Schuckert, and therefore he has placed the spiral springs of his ergometer in cylindrical cases.

When the spring is placed with its axis coincidental with that of the machine, no such error can be introduced, and the friction of a spring against a case is avoided.

When a continuous record of work is required, a cylinder, not shown in the figure, is placed at the dial end of the instrument, and is driven at a speed proportional to the speed of driving. It carries a band of paper which receives a continuous trace from three self-feeding ink-pens: one pen is attached to the lever which is moved by the extension of the spring, and it writes ordinates directly proportional to the amount of extension of the spring at any instant; the second pen, attached to the lever of an electro-magnet magnetised by a current controlled by a seconds pendulum, describes a V-shaped mark at each second; the third pen traces a datum line to which the ordinates are perpendicular. The area traced out is of course the product of the two variables, and is proportional to the total work transmitted. The recording drum may be made to revolve at any convenient ratio to the revolutions of the belt wheels. We are indebted to Mr. Smith for the loan of the figure which illustrates this notice.

NOTES

We are authorised to state that there is no truth in the rumour that Mr. Oscar Dickson intends to equip an Antarctic Expedition under the command of Baron Nordenskjöld.

The Rev. Dr. Salmon, Regius Professor of Divinity in Trinity College, Dublin, has been selected by the Institute of France to fill its vacant foreign membership.

According to the constant practice of the French Academy of Sciences, the seat occupied by M. Jamin in the Section of Physics is considered as vacant, and a new election will take place.

A meeting was recently held in the Hall of the Institution of Civil Engineers, Great George Street, Westminster, to consider what steps should be taken to raise an Engineers' Memorial to the late Sir William Siemens. Sir Joseph Bazalgette, as President of the Institution, was asked to preside. The Chairman pointed out that a general desire had been expressed among engineers that some memorial should be raised as a recognition of the great merits and important services rendered to engineering by Sir William Siemens. It has been ascertained that it would be agreeable to the authorities of Westminster Abbey that a window should be placed in that building to the memory of the deceased. Possibly the cost of such a window might amount to

between 700*l.* and 800*l.* The meeting agreed "that it would be very desirable to commemorate the distinguished character and attainments of the late Sir William Siemens by erecting to his memory a window in Westminster Abbey." It was determined to limit the subscription in the first instance to one guinea. A committee was appointed to carry out the project.

THE ceremony of laying the foundation-stone of the building which is to be erected, under the name of Alexandra House, at the charge of Mr. Francis Cook, as a home for 100 of the female students attending classes at the Royal College of Music, the South Kensington Museum, and other art and science schools in the neighbourhood, was performed on Monday afternoon by the Princess of Wales in the presence of a large assemblage of gentlemen and ladies. Mr. Cook deserves all credit for his enlightened liberality, and we have no doubt the home which he has founded will be a valuable aid both to the South Kensington classes and the College of Music. At the same time we may remind our readers that a similar institution has been successfully at work for a considerable time in Byng Place for female students attending University College and other institutions for the higher education of women.

WE hope to be able in an early number to consider at length the report of the City Companies Commission. Meantime, among other suggestions of the Commission, we may note their recommendation to appoint by Act of Parliament a Commission to undertake (1) the application of a portion of the corporate incomes of the Companies respectively to objects of acknowledged public utility; (2) the better application of the trust incomes of the Companies; (3) should it prove practicable, the reorganisation of the Constitution of the Companies. The Commission moreover recommend that by the terms of such Act "objects of acknowledged public utility" be defined as scholastic and scientific objects, *i.e.* elementary education, secondary education, classical education, scientific research.

THE International Forestry Exhibition was opened on Tuesday afternoon at Edinburgh by the Marquess of Lothian, in the presence of a large company. Many foreign Governments were represented, and the Lord Provost and magistrates of Edinburgh attended in their official capacity. The Marquess of Lothian, in opening the Exhibition, said that a special object was the better forestry education of the country. The United Kingdom had more property in the world than any other nation; but in this particular it was behind other nations. We were the only country that had not a school of forestry, and we had to send our young men abroad to gain the necessary knowledge. That, surely, was not right, and he hoped that out of that Exhibition there would come a school for forestry which might possibly be located in Edinburgh. They had every possible advantage there; they had the Botanic Gardens, the Arboretum, the University, and the Highland Society. All these bodies took an interest in the matter, and it only required that opportunity should be given for the practical part of the work. It was not too much to hope that before long, if the money were got, they might see a school of forestry in Scotland. He appealed to the public to make the enterprise a success, and, amid hearty cheers, declared the Exhibition open.

THE Anniversary Meeting of the Sanitary Institute of Great Britain will be held in the Theatre of the Royal Institution, Albemarle Street, on Thursday, July 10, at 3 p.m. The chair will be taken by the Right Hon. Earl Fortescue, and an address will be delivered by H. C. Bartlett, Ph.D., F.C.S., entitled "Some of the Present Aspects of Practical Sanitation," and the Medals and Certificates awarded to the successful exhibitors at the Exhibition at Glasgow, in 1883, will be presented.

THE Society of Chemical Industry will hold its annual meeting at Newcastle-on-Tyne on July 9 and following days. The meeting at Newcastle is looked forward to with great interest by the members of the Society throughout the country, for Tyneside is associated more closely than any other district with the birth and development of the chief of our great chemical manufacturing industries, and the committee of the Newcastle section, under the chairmanship of Mr. J. C. Stevenson, M.P., are doing their utmost to render the visit of the members to Newcastle in every way a memorable one.

MR. SIDNEY LUPTON, Assistant Master at Harrow School, has recently compiled and published some numerical tables and constants in elementary science which we can fairly recommend to our readers. It is a little book of about 100 pages, which of course possesses no claim to originality, the whole skill of the compiler being shown in the selection of materials which he has made. The book deals with numbers and measures, heat, light, sound, electricity, chemistry, and physiography; the latter division being wide enough to include tables of logarithms.

WE have received from the Bureau des Longitudes their "Annuaire" for the present year, which seems thicker and more complete than any of its predecessors, well worth the money it costs (1*s.* 3*d.*) even to the English reader, on account of the very valuable tables which it contains touching astronomical and geographical subjects. We notice in the present edition a very complete table of the different comets, which alone would make it a necessity in any astronomical establishment. The semi-popular article published in the "Annuaire" for this year is entitled "Sur les Grands Fleaux de la Nature"; it is by M. Faye, and is well worth reading.

M. MONTIGNY has recently published a pamphlet on the influence of the atmosphere in the apparition of colours seen in the scintillation of stars. In it he draws attention to the possibility of there being some connection between these colours and the coming weather. He has previously noticed that there is a great predominance of blue in the scintillating colour when rain is approaching, and he is now so convinced of the accuracy of this forecast that it is included among others in the *Bulletin Météorologique* published by the Observatory of Brussels. He gives the following forecast for the coming years:—"We may hope that we are happily quit of the period of wet years which commenced in 1876, and that we have already entered a series of fine years, or rather of more regular years as far as rain is concerned." *Nous verrons ce que nous verrons.*

OUR botanical readers may be interested to know that Herr F. Soácha of the Bürghschule, Deutschbrod, Bohemia, is preparing for publication a Flora of Austria-Hungary, which will contain specimens of the plants described. Those desiring to know the terms of subscription should communicate with Herr Soácha.

THE following are some of the special questions which have been arranged for discussion at the next Social Science Congress, which is to be held at Birmingham on September 17–24:—How far are the requirements of the country for well-trained teachers in elementary schools met by the pupil-teacher system and the existing training colleges? In testing the efficiency of schools should processes or "results" be chiefly regarded? Health—1. What is the best method of dealing with (*a*) town sewage, (*b*) the products of house and street scavenging, and (*c*) the products of combustion? 2. What are the best means, legislative or other, of securing those improvements in the dwellings of the poor which are essential to the welfare of the community? 3. How far may the average death-rate of a population be considered

an efficient test of its sanitary condition; and by what means can the high death-rate of children be reduced?

THE Pavlovsk Observatory has been, since 1882, in possession of two subterranean lines, each one kilometre long, and situated, one of them in the direction of the magnetic meridian, and the other perpendicular to it; and Dr. Wild communicates to the St. Petersburg Academy of Sciences (*Bulletin*, vol. xxix. No. 2) the following interesting results of his observations on terrestrial currents (the method of observation has already been described in the *Memoirs* of the Academy, vol. xxxi.):—The terrestrial current altogether does not manifest itself as a current which would flow for a time in one direction and then would slowly change it, but in the shape of more or less strong alternate currents, which rapidly change their direction. The east and west force is generally stronger than that of north and south. The observations on the regulation days do not show any diurnal periodicity, neither in the force of the current nor in the number of oscillations; but the average of the twenty-four regulation days of the year (September 1882 to September 1883) disclose such a periodicity, however feeble, namely, a maximum between 4 and 5 a.m. and a minimum at 8 p.m. for the meridional line, as also a maximum at 8 a.m. and a minimum at 1 p.m. for the other line. As soon as the force of the terrestrial current is on the increase, the magnetical instruments display perturbations which usually increase with the force of the terrestrial currents, without being, however, proportionate to them. If, according to Sir G. B. Airy, the north and south current be compared with the variations of declination, and the other current with horizontal intensity, both perturbations are often very equal, but those of the currents precede those of the terrestrial magnetism by at least five minutes. This retardation may explain the want of proportion between the variations of the current and those of the terrestrial magnetism, which proportion is the more wanting as the variations of the current are frequent and alternate. From these alternations Dr. Wild concludes that "terrestrial currents are always the primary cause of magnetic perturbations, but not of periodical variations of the magnetic elements."

SOME forty years ago Dr. Joule raised the question whether a body that is magnetised undergoes any change in its temperature; but the question has not yet received a definite solution, the rise of temperature which accompanies magnetisation being ascribed by some to induction currents, and not directly to magnetism. While recognising the influence of the former, Mr. Borgman has tried to show that there is also a change of temperature due to magnetisation and demagnetisation, and that the amount of heat thus disengaged is proportionate to the squares of the temporary magnetism. M. Bachmetieff, having made, at the University of Zurich, an extensive series of experiments, the first part of which is now published in the *Journal of the Russian Chemical Society* (vol. xvi. fasc. 3), arrives at the conclusion that magnetism, *by itself*, produces variations of temperature in magnetised bodies, and that this "magnetic heat" is equal to the product of the magnetic moment by the magnetising force multiplied by a constant; it increases also, within a certain limit, with the frequency of the interruptions of the magnetising current, and increases still more when the direction of the current is alternately changed. Its amount is not equal throughout the length of an iron cylinder, reaching its maximum about its middle and decreasing towards its ends. Its cause must be searched for in purely mechanical forces, and it depends upon the speed of rotation of the molecular magnets.

ABOUT the middle of June the inhabitants of Moscow were puzzled to see immense masses of insects, taken at first for locusts, flying east in thick clouds over the city. It appears now that the insects were dragon-flies (*Libellula quadrimaculata* and *L. rufa*) belonging to the rapacious species which live on other insects.

COUNT UVAROFF continues his archæological explorations in the Government of Smolensk, and recently he has found very interesting remains of rude pots containing ashes and bones which are supposed to be burial remains of the Krivitchi, who had the custom, according to the Nestorian annals, of thus burying their dead.

DR. CHAVANNE, who is travelling on the Congo for the Brussels National Institute of Geography, has established a meteorological observatory at Boma. Mr. Stanley has transferred the site of his station of Vivi to a table-land some 1500 metres to the north; and a railway from the new station to the Congo is in course of construction. A new station, called Sette-Cana, has also been established at the mouth of the small River Sette. Numerous small wooden houses are being made in Belgium to be transported to the new Vivi. A sanatorium has been constructed at Boma.

A TELEGRAM from Krasnovodsk gives the true history of the Uzboi, the ancient bed of the Amu Daria. For 250 versts, from Sarykamish to Bola Ishem, there is no stream, this locality presenting a series of desiccated marshes and lakes. At Akkal there is no channel. This part of the Uzboi, which evidently formed an estuary of the Caspian and partially fed the Sarykamish lake, has been silted up from the sea. The project for uniting the Amu Daria with the Caspian requires several hundred versts of canals.

M. JAUBERT has organised in the Great Tower of the Trocadéro Palace a repetition of the experiments tried by Pascal in the Tour Saint Jacques, on the diminution of barometric pressure with increase of altitude. He is also arranging a Foucault pendulum which will oscillate in the same condition as in the Pantheon, with a contrivance for making its vibration perpetual.

THE additions to the Zoological Society's Gardens during the past week include an Indian Wild Dog (*Canis primævus*) from India, presented by Mr. T. A. Bulkeley; a Brush-tailed Kangaroo (*Petrogale penicillata* ♂) from New South Wales, presented by Mr. J. Abrahams; a White-collared Mangabey (*Cercocebus collaris* ♂) from West Africa, presented by Mrs. Du Heaume; a Black-eared Marmoset (*Hapale penicillata* ♀) from South-East Brazil, presented by Mrs. C. Spencer Stanhope; a Guianan Tree Porcupine (*Sphingurus insidiosus*), a Rough Fox (*Canis rudis*) from British Guiana, presented by Mr. G. H. Hawtayne, C.M.Z.S.; a Laughing Kingfisher (*Dacelo giganteus*) from Australia, presented by Mrs. W. Moir; two Chaplain Crows (*Corvus capellanus*) from Persia, presented by Mr. B. T. Ffinch; a European Pond Tortoise (*Emys europæa*), two Spotted Salamanders (*Salamandra maculosa*), European, presented by Mr. J. Satcherd; two Algerian Tropidosaures (*Tropidosaura algira*), three Rapid Spine-foot Lizards (*Acanthodactylus vulgaris*) from North Africa, presented by Mr. W. C. Tait, C.M.Z.S.; an Adorned Ceratophyrs (*Ceratophyrs ornata*) from South America, presented by Capt. Hairby; an Orange-winged Amazon (*Chrysotis amazonica*) from South America, a St. Thomas's Conure (*Conurus xantholæmus*) from St. Thomas, W.I., a Yellow Conure (*Conurus solstitialis*) from Guiana, two Passerine Parrots (*Psittacula passerina*) from British Guiana, deposited; a Bengal Vulture (*Gyps bengalensis*) from India, two Coscoroba Swans (*Cygnus coscoroba*) from Chili, three Turquoisine Parrakeets (*Euphema pulchella*) from New South Wales, purchased; two Black Guillemots (*Uria grylle*) from Ireland, received in exchange; a Hog Deer (*Cervus porcinus* ♀), four Himalayan Monauls (*Lophophorus impeyanus*), five Chilian Pintails (*Dafila spinicauda*), five Summer Ducks (*Æx sponsa*), bred in the Gardens.

THE COMPOSITION OF CHLOROPHYLL

AMONG recent papers on chlorophyll those of Hansen, assistant to Prof. Sachs, are worthy of notice.[1]

Dr. Hansen has applied the saponification method, found so useful by Prof. Kühne[2] in his researches on the chromophanes, to the study of chlorophyll, and has been led to some very important conclusions. It may be remembered that Fremy tried to show that the green chlorophyll colouring matter consists of a blue and a yellow constituent. He mixed an ethereal chlorophyll solution with hydrochloric acid, when two layers formed—a lower blue layer and an upper yellow ethereal layer. The blue colouring matter was named by Fremy *phyllocyanin* and the yellow *phylloxanthin*.

Hansen shows that this is not due to a splitting up of the chlorophyll green into a blue and a yellow component, but only an incomplete separation of the chlorophyll green from the chlorophyll yellow, the former becoming changed to blue by the hydrochloric acid, and he further shows that an ethereal solution of pure chlorophyll green treated with hydrochloric acid does *not* furnish any yellow constituent, the ethereal layer remaining colourless. Fremy himself, however, abandoned the view that chlorophyll consists of two colouring matters.

The views of Kraus are so well known that it is hardly necessary to recapitulate them here, but I may be permitted to recall to mind that he supposed he had decomposed chlorophyll green into a blue green and a yellow component. He mixed an ordinary alcohol chlorophyll solution with benzol, and obtained two layers, an underlying yellow alcoholic layer and an upper blue-green layer. The blue-green Kraus named *cyanophyll*, the yellow *xanthophyll*.[3] Hansen shows, however, that Kraus is wrong in supposing that a *decomposition* of the green colouring matter into a blue-green and a yellow has taken place, as it is only an *incomplete separation* of the chlorophyll green from the chlorophyll yellow. Kraus's *cyanophyll* therefore is nothing more than an ordinary chlorophyll solution out of which a part of the yellow colouring matter has been removed. Both Fremy and Kraus were correct in assuming that a yellow and a green constituent were present, but incorrect in supposing they existed *in combination*; the correct view now is that *they exist side by side*. In other words, chlorophyll is merely a *mixture* of these colouring matters.[4] [I think it necessary here to give Conrad's view, viz. that Kraus had effected a decomposition of the chlorophyll by the use of water, as Kraus used weak alcohol. Conrad showed that by using strong alcohol no yellow pigment could be got into solution by means of benzol. Cf. Sachs' "Botany," 2nd English ed. p. 760.] In the preparation of pure chlorophyll Hansen used young plants of wheat at the time of their growth when the fourth leaf is formed. Then the plant contains only protoplasm, chlorophyll, and cellulose. The spectra of the solutions were observed as in the experiments of Kühne,[5] on the pigments of vertebrate eyes, and of Krukenberg[6] on those of various animals, by means of sunlight thrown into the slit by a heliostat, a large chemical spectroscope having been used.

The leaves of the plants are first boiled to remove extractives, the water poured off, and the material washed with water until the wash water is quite clear. It is then quickly dried at a low temperature, and afterwards extracted with alcohol. Hansen states that the boiling does not alter the chlorophyll, since the plant residue, after boiling, gives the same bands as the living leaf. For the alcoholic extraction 96 per cent. alcohol was used, and it was carried on in a dark room to avoid decomposition of the chlorophyll by light. A second extraction was also carried out, and the alcohol left in contact with the residue until the former assumed a dark green colour.

The united alcoholic solutions were then concentrated and *saponified*. Hansen had previously found that he could separate out, in the case of the colouring matter of blossoms, by means of saponification, the yellow colouring matters from the fats in combination with them, as Kühne had previously done in the case of the *chromophanes* and other pigments, and not only did he get the pigments fat-free, but also in a crystalline state.

3 "Zur Kenntniss der Chlorophyllfarbstoffe," &c., Stuttgart, 1872.

4 *Ibid.* 5 *Loc. cit.*

6 Krukenberg, "Vergleichend physiol. Studien," 1880-82.

The saponifying was carried out as follows:—The leaf-extract (alcoholic), after concentration, was treated with caustic soda solution in not too great amount, but the amount to be added has to be determined by the quantity of chlorophyll present. As a general rule Hansen used 40–50 c.c. (of a 1NaHO to $5H_2O$ solution) to 2½ c.c. chlorophyll solution obtained by concentration of 16–20 c.c. alcohol extract. When the alcoholic solution boils, the caustic soda is added drop by drop, the liquid being stirred. After the alcohol is driven off, water is poured in, and the heating continued. After the evaporation of a great part of the water, alcohol is added once more, and the saponification is ended. When the alcohol has evaporated, the soap lees is diluted with water and an excess of chloride of sodium added to separate the soap, which precipitates in a granular form. It is then shaken in a separating funnel with petroleum ether, which assumes a dark yellow colour, since it removes only the yellow constituent; this extraction is repeated as long as the petroleum ether is coloured. On evaporation of the latter, the *yellow* constituent is left.[1]

The soap is now treated with ether, which removes various impurities, and a little colouring matter, and then with ether containing alcohol, which removes the *green* constituent from the soap.

Hansen asserts, and gives his reasons for the assertion, that no change takes place in the pigments by the above treatment.

The *yellow* constituent crystallises in dark yellow needles out of the petroleum ether, and gives all the reactions of a lipochrome, both as regards spectrum and chemical characters.

The *green* constituent can be obtained out of the ether-alcohol solution after occasional filtering and evaporation of the ether, and any yellow colouring matter adhering to it can be removed with petroleum ether. For the usual reactions this pigment answers very well, but for further study it has to be purified from water, &c., which is done by further treatment with ether-alcohol solution. Finally the pigment crystallises out in spherical crystals, which show a beautifully-marked cross with crossed Nicols. Even a drop of the solution allowed to evaporate on a microscopic slide allows the crystals to be seen, thousands of small "sphærocrystals" appearing on the evaporation of the ether. Hansen shows that the idea that plants contain but a small quantity of chlorophyll is erroneous, as he has obtained out of 450 grams dried wheat leaves as much as three to four grams solid colouring matter.

Chlorophyll green is opaque in the solid state, and appears of a black-green colour, and in that state possesses no fluorescence, but in solution possesses the usual red fluorescence. Its various chemical characters are given at length in the original paper, and it is shown that some of the changes with acids described by authors are not due to their action on pure chlorophyll green, but on other unknown bodies. It is free from sulphur and from iron. The elementary analyses agree very closely, and calculated for the ash-free substance are the following:—

	I.			II.	
C.	67·26	per cent.	...	67·94	per cent.
H.	10·63	,,	...	10·36	,,
O.	16·97	,,	...	16·12	,,
N.	5·12	,,	...	5·55	,,
	99·98			99·97	

The amount of carbon is 1 per cent. too low in both cases.

Chlorophyll yellow occurs in small quantity as compared with chlorophyll green, in the proportion of about 1 to 100. Its solutions show no fluorescence, and statements to the contrary have been based upon deductions drawn from imperfect methods of separation. It possesses the reactions of Krukenberg's *lipochromes*,[2] in the solid state, namely: a blue coloration with sulphuric acid, the same with nitric acid, and a green-blue with a mixture of iodine in potassium iodide. It shows three bands in the blue half of the spectrum, but no absorption of red, and agrees in spectrum with the yellow colouring matter of etiolated leaves (*etiolin*), which is incorrectly represented by some as possessing bands in the red part of the spectrum. Chlorophyll green possesses four bands in the red half of the spectrum; they agree with the four bands of the ordinary chlorophyll solutions.

With regard to Tschirsch's "pure chlorophyll," which, it may be remembered, was described in the *Journal of the Chemical Society*, February 1884, with the remark that the writer "reserved to"

1 Compare Kühne, *loc. cit.*, Band iv. Heft 3, 1882.

2 Krukenberg, *loc. cit.*, "Zur Kenntniss der Verbreitung der Lipochrome im Thierreiche," Zweite Reihe, 3te Abth. 1882.

himself "the right of examining it further," Hansen observes that "it possesses all the reactions of the usual chlorophyll sauce."[1]

In a second paper[2] Hansen figures the spectra of chlorophyll green and chlorophyll yellow. His researches will, no doubt, be found useful by students of vegetable chromatology.

C. A. MacMunn

RECENT MORPHOLOGICAL SPECULATIONS[3]

II.—*The Origin of Vertebrates*

FIFTEEN or sixteen years ago Kowalevsky's researches on the development of Amphioxus and of Ascidians seemed to be solving the question of the origin of Vertebrates. The discovery of the larval notochord in Ascidians, and the recognition of the homology of their pharyngeal clefts with the gill-slits of Vertebrates, made it necessary to acknowledge the close relationship of the two, as had been already foreshadowed by Herbert Spencer; while the yet undisputed affinity of Ascidians to Mollusks brought Vertebrates and Invertebrates together in an unbroken line. But as new knowledge brought Ascidians closer to Vertebrates, it undermined their claims to molluscan affinities; and as the doctrine of degeneration grew up, in the hands of Dohrn and Lankester, it taught that Ascidians, and Amphioxus too for that matter, were not really *ancestors* of the higher Vertebrata, but only degenerate descendants of such ancestors, poor cousins, as it were, of the higher Vertebrates. The lines by which Vertebrates had sprung from Invertebrates, the common ancestor of Ascidians, Amphioxus, and the higher Vertebrates, had still to be sought for.

Two leading theories have been formulated, and are still under discussion. The first, identified with the names of Semper and Dohrn, maintains that the nearest allies of the Vertebrates must be looked for among the Chætopod worms, the dorsal surface and spinal cord of the former corresponding morphologically with the ventral surface of the latter, and its gangliated nerve-cord. On the second view, with which we may associate the names of Balfour and Hubrecht, we must take the ancestor of the Vertebrates to have been some segmented worm, descended from the same unsegmented types as the Chætopods, but in which the two nerve-cords, at first lateral like those of Nemertines, had coalesced dorsally instead of ventrally, to form a median nervous system.

Our discussion of the first of these theories may be made clearer if we use the words "neural" and "hæmal" instead of "dorsal" and "ventral," for the gist of the theory is that in the two groups *neural* and *hæmal* surfaces remain constant, but what is dorsal in the one is ventral in the other.

In the Chætopods, say the advocates of this theory, we have a group of regularly segmented animals, not so far specialised but that we might well conceive ancestors like them to have developed into Vertebrates; they point to the relations of the nervous, vascular, and alimentary systems, and to the development of the mesoblast, as being closely parallel in the two groups; and they try to find traces or representatives in Chætopods of such typically Vertebrate possessions as notochord, gill-clefts, and swimming-bladder.

At the very outset a difficulty arises which is perhaps the greatest the theory encounters. The mouth of Chætopods is neurally placed, and surrounded by a nerve-ring; in Vertebrates it is hæmal, and it does not pierce any part of the nervous axis. Dohrn has attempted to overcome this objection. The present mouth of Vertebrates, he says, is not identical with the Invertebrate mouth; it is a distinct and secondary structure; it arises late in development, whereas in other classes the "stomodæum" or primitive oral invagination appears very early. Moreover, in the majority of Vertebrates the mouth does not persist in the position it first appears in; it arises some way off from the anterior end of the body, and in Elasmobranchs, some Ganoids, and Myxinoids it remains there, but in all other Vertebrates it becomes terminal. If we assume, then, that the mouth in existing Vertebrates is secondary, there must have been a time when it did not exist, and when its functions were performed by another or primary mouth. It has been suggested that in the *hypophysis cerebri* or "pituitary body" we have, possibly, a remnant of this primary mouth. The hypophysis cerebri appears first as an ectodermic involution, usually arising from the stomodæum; but in the lamprey, Götte, Scott, and Dohrn have shown that it arises from the ectoderm which lies anterior to the mouth. It is here, in fact, a little pit of ectoderm, placed between those other two ectodermic pits, which are to become the nose and the mouth.

If this involution ever pierced the brain and opened upon the neural surface, the fore-brain would then be evidently homologous with the supra-œsophageal ganglion of Invertebrates, or ganglion of the præ-oral lobe. A great deal may be said for thus regarding the fore-brain as distinct from the remaining nervous system; it resembles the supra-œsophageal ganglion of the Invertebrata in its close connection with the optic and olfactory organs, and in supplying only organs of sense. There is evidence to show that the third nerve belongs to the cranio-spinal series of segmental nerves, and that the olfactory and optic nerves have a different nature. If this be so, the mid-brain, giving origin to the third nerve, would appear not to have part in the ganglion of the præ-oral lobe. The termination of the notochord directly behind the fore-brain is an additional argument in favour of the morphological distinctness of the latter structure.

Thus if we follow back the genealogical record of the Vertebrates, we find that at one period their ancestors had a mouth upon the neural surface; later, two openings into the alimentary canal appear, one on the neural and one on the hæmal surface; still later the latter gains the ascendancy, and alone remains to the present time. This secondary mouth must have arisen from some pre-existing structure; it could not have originated as a simple depression of the outer skin which deepened and ultimately fused with the alimentary canal; and the only pre-existing organs which could furnish such a passage from the exterior into the alimentary tract are the gill-slits. We must conceive this Vertebrate ancestor as an animal with an intestine which opened anteriorly by a median mouth on its neural surface, and laterally by a series of segmentally situated gill-slits. The mouth took in water, which flowed out over the gill-arches just as it does still in the lower Vertebrates. If from any reason, such as the animal lying like the modern Annelids on its neural surface, it obtained a purer supply of water by taking it in through some of the gill-slits, it is conceivable that a pair of these slits assumed that office, and that by the exercise of this power the gill-slits became gradually larger, and ultimately fused in the middle line. The suctorial power thus acquired to take in water for the purposes of respiration was also of use in obtaining food, and thus a median hæmal suctorial mouth arose, such as the Myxinoids now possess. There is much evidence to show that the ancestral Vertebrate possessed a suctorial mouth which subsequently became modified for biting, and was carried forward to the front of the head. Embryology supplies the following arguments in favour of regarding the mouth as formed from the coalescence of a pair of gill-slits. It lies close against the gill-slits, it is separated from them by a gill-arch, it arises about the same time in the embryo, it opens into the alimentary canal; finally, in some Teleosteans, *Belone*, *Hippocampus*, and *Gobius*, the mouth first appears as two lateral openings, which afterwards fuse in the middle line.

Admitting that the mouth is formed of two gill-slits, we have to see from what structures in an Annelid such gill-slits could be derived. In many Chætopods no part of the body is set apart to perform the function of respiration. Where there are no gills the blood is commonly aërated in the walls of the alimentary canal, water being taken in at either end, and when charged with the waste products of respiration, it is expelled through the same opening. In some cases, as in *Hesione*, the surface with which the water comes in contact is increased by a pair of lateral sacs or diverticula. It is obvious that with such a respiratory apparatus it would be advantageous if there was an exit for the respired water distinct from its entrance, so that the blood should always be in contact with pure water. Such an exit would be formed by fusion of the respiratory diverticula with the body-wall and subsequent rupture of the latter at the points of fusion. And the apertures in the tentacles of Actiniæ and the perforated liver-diverticula of Eolis are adduced as analogous instances of such perforation.

Another suggestion which has been made to account for the origin of gill-slits is that the inner ends of some of the segmental organs gained an entrance into the alimentary tract, and, changing their function, gave rise to gill-slits.

By these steps a Vertebrate has been reduced to an Annelid structure, but certain questions which have arisen in the development of this theory remain to be answered. One is whether the

[1] Tschirsch only obtained his chlorophyll in the form of "blackish-green drops."

[2] *Loc. cit.*

[3] Continued from p. 69.

mouth is formed from the most anterior pair of gill-slits. If the trabeculæ cranii are gill-arches, the mouth is not the first. Some authorities consider the nasal sacs as modified gill-slits; they are primitively double, and where we find them single, as in Amphioxus and Cyclostomes, it is due to secondary processes.

In his "Monograph on the Development of the Elasmobranch Fishes," Balfour has pointed out that the histological structure of the spinal cord in Vertebrates is exactly what would be found if, by mechanical folding, the two lateral halves of the nerve-cord of an Annelid became bent toward one another, whilst the external skin was pushed into the groove between them. If this folding were completed, so that the external epithelium formed a canal surrounded by nervous tissues, the white and gray matter would assume the same relative position that they possess in the spinal cord of Vertebrates. The nerves would then arise not laterally, but from the extreme ventral summit, and would thus correspond with the posterior roots of the Vertebrate spinal cord, which, as Balfour has shown, grow out from the extreme dorsal summit of the neural canal, a position comparable with the ventral summit of the Annelid nervous system. In Amphibia the primitive medullary plate (or modified area of dorsal epiblast which is to fold in and form the medullary groove), although elsewhere single, shows signs of being formed of two symmetrical halves, and in both embryo and adult the neural tube has a structure which points to its origin from the coalescence of two lateral cords.

The direction of the blood current, which flows from behind forwards on the hæmal, and from before backwards on the neural, surface, agrees in Chætopods and Vertebrates if the surfaces be reversed, and the hypothesis of reversal presents no great difficulties in the case of a cylindrical animal swimming in the sea.

In connection with this theory it is interesting to note that Eisig has instituted a comparison between the lateral sense-organs in the Capitellidæ (a family of Chætopods) and the lateral line of fishes, and he further compares the "siphon" of the same Chætopods with that obscure rod of tissue split off from the alimentary tract of fishes and Amphibia, the sub-notochordal rod.

The notochord is one of the most characteristic Vertebrate structures, and if the theory propounded above be true, we should expect to find very distinct rudiments of such a structure amongst the Chætopods, but although numerous organs have been interpreted as such, Balfour states that none of these interpretations will bear examination. Quite recently Nussbaum has found in the cockroach a longitudinal string of cells lying upon the nerve-chain, which in its development bears a striking resemblance to the notochord of Vertebrates, and Vejdovsky has described a similar structure in Oligochæta, developed, however, from the mesoderm, under the name of neurochord.

The supporters of the second theory, which we have connected with the names of Balfour and Hubrecht, claim that they have found an organ in one class of the Invertebrata which is comparable to the notochord of Vertebrata.

Balfour in the "Elasmobranch Fishes," whilst combating the Chætopod origin of Vertebrates, suggested that Vertebrates have descended from the same unsegmented stock as the Chætopods, but through some other line which has entirely disappeared. They have thus acquired similar segmental and other organs. In this line of ancestors he imagines that the primitive lateral nerve cords have tended to coalesce dorsally instead of ventrally. In his "Comparative Embryology" he repeats these views, and adds that their probability has been increased by the researches of Hubrecht, who has shown that in some Nemertines the nerve-cords approach each other very closely in the median dorsal line. Hubrecht has quite recently amplified these views by suggesting that "the proboscis of Nemertines, which arises as an invaginable structure, and which passes through a part of the cerebral ganglion, is homologous with that rudimentary organ which is found in the whole series of Vertebrates without exception—the hypophysis cerebri. The proboscidian sheath of the Nemertines is comparable in situation (and development?) with the notochord of Vertebrates."

The first of these two positions is supported by the facts of development. Although the details of the ontogenetic origin of the Nemertine proboscis are still wanting, the broad fact that it arises, like the hypophysis cerebri, as an invagination of the epiblast, has been established.

These organs further resemble each other in the shifting of their external opening, which is in some cases on the outer surface, in others on the dorsal wall of the alimentary canal just within the mouth.

In this comparison between the proboscis of Nemertines and the hypophysis cerebri, the connection of the latter with the brain and its relation to the anterior end of the notochord, must be especially borne in mind. The proboscis passes backward, between the anterior thickenings which form the brain, the two lateral halves of which are connected by a thick nerve commissure ventral to the proboscis, and by a thin strand dorsal to it. Thus the proboscis pierces a ring of nervous tissue, and the proboscis sheath reaches forward to the level of this nervous commissure. This region, then, would correspond to that part of the vertebrate brain to which the hypophysis cerebri is attached and close behind which the notochord terminates, and would thus separate off the fore-brain from the remaining nervous system. In connection with this it is a very significant fact that the superior lobes of the Nemertine brain give rise to the nerves which supply the sense organs, while the strong nerve which supplies the anterior region of the œsophagus originates in the inferior lobes. The one pair of these lobes may thus have been perpetuated as the fore-brain, and the other as the rest of the nervous system.

The sheath of the proboscis corresponds very accurately in its position to the notochord, but unfortunately the knowledge we possess of its development is not great. Barrois and Salensky have attributed a mesoblastic origin to it, the latter, however, noting a connection between the first origin of the œsophagus and proboscis. Hoffman has stated that part of the proboscis is split off the dorsal surface of the alimentary canal, whilst the muscular proboscis sheath is mesoblastic in origin. Hubrecht suggests that possibly the formation of the inner part of the proboscis sheath has been mistaken for the proboscis. If this suggestion prove true, then the proboscis sheath agrees both in position and origin with the notochord of Vertebrates.

The fully-developed notochord is a solid rod, whereas the proboscis sheath is a hollow tube. This, however, is no very serious objection to their homology; and recently Lieberkühn and Braun have shown that the notochord arises at first as a hollow tubiform structure, whilst in old specimens of *Cerebratulus* (a Nemertine) the posterior end of the proboscis sheath is nearly or quite filled up with continuous cellular tissue.

We have unfortunately too little knowledge at present to institute a comparison between the other organs of Nemertines and Vertebrates. Attention should, however, be called to the ciliated lateral pits upon the head. These arise from the most anterior part of the œsophagus in front of the mouth. They bud out from the walls of the œsophagus, and are in this stage directly comparable to similar diverticula which arise in the same region in the larva of *Balanoglossus*, and which there give rise to the first pair of branchial slits. These diverticula become finally cut off from the œsophagus, but enter into connection with epiblastic invaginations, and are thus placed in communication with the sea-water. In Schizonemertines their inner end is in connection with the brain; the latter contains hæmoglobin, and so they subserve respiration. In Hoplonemertines, however, although their development is similar, they apparently are modified for a sensory, possibly an olfactory, function. In connection with these structures, Hubrecht calls attention to some of the results of Hatschek's recent researches on the development of Amphioxus. In this animal there are two lateral hypoblastic diverticula growing out from the anterior part of the œsophagus in front of the mouth. These differ both in their nature and development from the archenteric diverticula, or from the branchial outgrowths. They are at first symmetrical, but have a different fate. They are both constricted off from the hypoblast: the left one communicates with the exterior by a ciliated opening which appears in the epiblast; the right one forms an epithelial lining to the præoral body region. The left one has been looked upon as a special sense organ of the larva.

Finally it is impossible to overlook the bearing of Balanoglossus on our subject, although we are not yet in possession of all the facts that Mr. Bateson's (*Q.J.M.S.* No. xciv. April 1884) recent researches seem to have elicited. The pharyngeal slits of Balanoglossus have long been recognised as wonderfully like the gill-slits of Vertebrates, and on the other hand as totally unlike any structures possessed by animals outside the Chordata. But Bateson's researches have already shown that the developmental features of the nervous system and of the mesoblast are not less suggestive of the same kinship. For the mesoblast is developed from an anterior archenteric pouch with two posterior horns (exactly comparable with that described in the last paragraph as existing in Amphioxus) and two pairs of posterior pouches instead of the large number that Amphioxus possesses. And the fate

of the anterior pouch is almost identical in the two forms, for in Balanoglossus its left-hand division becomes lined by cilia and opens to the exterior, whereas its right-hand half degenerates into connective tissue. And as regards the nervous system (which in Balanoglossus contains no mesenteric canal as that of Amphioxus does) "it is only necessary to imagine the invagination of the dorsal nerve-cord to have been extended along the back (instead of being confined to the region of the collar) in order to reproduce the condition which is found in Amphioxus." But however much we may be struck by these relations of Balanoglossus, its own isolated position and the extreme difficulty of allying it to any other Invertebrate groups prevent it from throwing much light upon the Vertebrate pedigree. The claims of the two theories discussed above may be unaffected, however close the correspondence between Amphioxus and Balanoglossus may be shown to be; and as yet Balanoglossus seems to do little more than remind us of how remote a relative of the Vertebrates Amphioxus itself is. Amphioxus occupies such an outlying branch, so far from the main stem of the genealogical tree of Vertebrates, that the demonstration of its likeness to an isolated Invertebrate like Balanoglossus may, like its obvious relationship with the Tunicates, be of little use to us.

It is perhaps premature to judge between these two theories detailed above, or to accept either of them definitely as an indication of the origin of Vertebrates. But we must point out that the Chætopod theory lies under the great disadvantage of assuming as far distant ancestor of Vertebrates a class of animals that seem really to occupy an apical position in a certain line of development. The Chætopods seem to be so highly specialised, that we must be suspicious of taking them to be the origin of another great group, but rather consider them as the ultimate result of evolution in a particular direction. In general it must always, *a priori*, be unsafe to attempt to make the apex of one group the base of the next; and in all cases it must be better, and more consonant with the principles of evolution, to search for the closest relations of one group among the simpler and less specialised members of another.

A. E. S.

THE ROYAL SOCIETY OF CANADA

THE annual meeting of this Society was held at Ottawa, May 21-24, under the presidency of the Hon. P. J. O. Chauveau, LL.D., D.-ès-L.

The following papers were read in Section III. (Mathematical, Physical, and Chemical Sciences):—Electrical induction in underground and aërial metallic conductors, by F. N. Gisborne, C.E. The author proposed, in order to get rid of induction phenomena in telephone circuits, to connect sending and receiving telephones by means of pairs of twisted and insulated wires. He described experiments made with a section of cable about 3000 feet in length and laid underground between two of the Departmental Buildings at Ottawa. The cable contained twenty indifferently insulated wires, which were divided into pairs, two wires being twisted together in each case, each pair constituting a metallic circuit, and one wire of each pair being used as a "return" instead of the earth plates usually employed. The experiments showed that if one of these pairs was used as a telephonic circuit, no induction effects could be observed in the others. The absence of induction effect he attributed to the equidistance of the two wires of a pair from any third wire and the equality and opposition of the currents flowing in them.—A particular case of the hydraulic ram or water hammer, by C. Baillargè, C.E.—On the form of the contracted liquid vein affecting the present theory of the science of hydraulics, by R. Steckel. Communicated by C. Baillargè, C.E.—The origin of crystalline rocks, by T. Sterry Hunt, LL.D., F.R.S. The author began by remarking that the problem of the origin of those rocks, both stratified and unstratified, which are made up chiefly of crystalline silicates, is essentially a chemical one. He then proceeded to review the history of the once famous dispute between the vulcanist and the neptunist schools in geology as to whether granite and other crystalline rocks were formed by igneous or by aqueous agencies, and showed from recent writers that the controversy is not yet settled. He noticed of the igneous school both the plutonic and the volcanic hypotheses of the origin of these rocks, and then considered the so-called metamorphic and metasomatic hypotheses, which would derive them by supposed chemical changes from materials either of igneous or of aqueous origin. The hypothesis of Werner was next discussed. This conceives all such rocks to have been successively deposited in a crystalline form from a chaotic watery liquid, which surrounded the primitive earth, and at an early time held in solution the whole of the materials of these rocks. The inadequacy of all of these hypotheses was pointed out, though it would appear that Werner's was the one nearest the truth. The author conceives that the crystalline rocks were formed by deposition from waters which successively dissolved and brought from subterranean sources the mineral elements. Their formation is illustrated by that of granitic veins, and that of zeolites—processes regarded as survivals of that which produced the earlier rocks. The true zeolites are but hydrated feldspars, while the minerals of the pectolitic group correspond to the protoxyd-silicates of the ancient rocks. The source of the elements in these rocks, according to the new hypothesis here proposed, was in the superficial layer which was the last-congealed portion of an igneous globe consolidating from the centre. In this primitive stratum, porous from contraction and impregnated with water, resting upon a heated anhydrous nucleus, and cooled by radiation, an aqueous circulation would be set up, giving rise to mineral springs. The waters of these dissolved and brought to the surface, there to be deposited, the quartz, the feldspars, and other mineral silicates, which, through successive ages, built up the great groups of crystalline stratified rocks, often so markedly concretionary in aspect. Exposed portions of the primitive silicated material would be subject to atmospheric decay and disintegration, giving rise to sediments of superficial origin, which would become intercalated with the deposits from subterranean sources. The reactions between the mineral solutions from below and the superficial materials were important in this connection, probably giving rise to certain common micaceous minerals; while dissolved silicates allied to pectolite, by their reaction with the magnesian salts, which then passed into the ocean waters, generated species like serpentine and pyroxene. This process of continued upward lixiviation of the primitive chaotic stratum would result in the production of a great overlying body of stratified acidic rocks, leaving below a basic residual and much diminished portion, the natural contraction of which would cause corrugations of the superincumbent stratified mass, such as are everywhere seen in these ancient rocks. The source of volcanic rocks is partly in this lower and more or less exhausted stratum of comparatively insoluble and basic ferriferous silicates, whence come melaphyres and basalts; partly in the secondary or acidic mass, which, softened by the combined agency of water and heat, may give rise to granitic and trachytic rocks; and partly also, it is conceived, in later aqueous deposits of superficial origin, which also may be brought within the influence of the central heat. This attempt to explain the genesis of crystalline rocks by the continued solvent action of subterranean waters on a primitive stratum of igneous origin the author designates the crenitic hypothesis, from the Greek κρήνη, *fons*. A preliminary statement of it was made by him to the National Academy of Sciences at Washington, April 15, 1884, and appears in the *American Naturalist* for June.—On the density and thermal expansion of aqueous solutions of copper sulphate, by Prof. J. G. MacGregor, D.Sc. The author gave the results of extended observations of the density of solutions of different concentration and at different temperatures. They show that the rate of variation of density with temperature increases with the temperature and with the percentage of salt in solution; that the density of any solution at low temperatures (below 20° C.) diminishes, as the temperature increases at a greater rate than that of water; that the ratio of the density of a solution to the density of water at the same temperature diminishes as the temperature increases; and certainly for many solutions, probably for all, attains a constant value within the temperature limits of the experiments (below 35°-50°); that, therefore, at about 40° C. the thermal expansion of solutions is the same as that of water at the same temperature. The experiments also substantiated a result formerly reached by Prof. Ewing and the author that very weak solutions of this salt have a smaller volume than the water used in making them. If then these solutions are made by the addition of anhydrous salt to water contraction must occur. The experiments show that the greatest contraction occurs in the case of a solution containing 1·34 per cent. of anhydrous salt, in which case the contraction is 0·0048. The solution containing 5·95 per cent. of anhydrous salt has the same volume as the water required to make it.—Blowpipe reactions in plaster of Paris tablets, by Prof. E. Haanel, Ph.D. This paper was a continuation of that presented to the Society last year. The author described the result of the treatment of copper with hydrobromic acid, and of iron and

selenide of mercury with hydriodic acid. He held the range of coatings *per se* for those tablets to be greater than for any other support used in blowpipe analysis, and described these coatings for selenium, tiemannite, arsenic, silver, alloys of bismuth, antimony, and lead with silver, galena, orpiment, realgar, mercury, tellurium, carbon, cadmium, and gold.—Description of an apparatus for distinguishing flame-colouring constituents when occurring together in an assay, by Prof. E. Haanel, Ph.D. The apparatus consists of a spectacle frame furnished for the left eye with plain colourless glass, and for the right eye with four glasses—red, green, violet, and blue. These glasses revolve on an axis, and can be brought either separately or in any combination before the eye of the operator.—"Essai sur la Constitution atomique de la Matière," by the Very Rev. T. E. Hamel, D.D.—The algebraical development of certain functions, by Prof. N. F. Dupuis, M.A.—Contributions to our knowledge of the iron ores of Ontario, by Prof. E. J. Chapman, Ph.D., LL.D. The paper contained a series of analyses of magnetic and other iron ores from samples obtained personally by the author from various parts of Ontario. The geological conditions of the deposits are also briefly given.—"Note sur une fait météorologique particulier à Quebec," by Rev. Prof. J. C. K. Laflamme, D.D.

Section IV. (Geological and Biological Sciences).—The following papers were read:—Note of observations in 1883 on the geology of a part of the north shore of Lake Superior, by A. R. C. Selwyn, LL.D., F.R.S. In these observations the author considered he was able to show that the great masses of columnar trap which form the summit of Thunder Cape, Pic Island, and McKay's Mountain were not part of a "crowning overflow," as they have been described to be, and newer than the Keweenian series, but that they are contemporaneous with the black slaty shales of the Animikie series, which immediately and conformably underlie them.—Revision of the Canadian Ranunculaceæ, by Prof. George Lawson, Ph.D. LL.D. (Halifax, N.S.). The author referred to his "Monograph of Ranunculaceæ," published in 1870, to the extensive collections that had been subsequently made, and to works published upon the North American flora, all of which enabled a fuller and more accurate description of Canadian ranunculaceous plants to be given now than was possible when the previous paper was prepared. The greater precision given to recent observation had also enabled the geographical range of these plants to be stated more fully. The striking diversity of modification in the form, number, and arrangement of the several parts of the flower and of the fruit in the several genera was pointed out. The number of Canadian species is 78 and of varieties 18: viz. Clematis 4, Anemone 14, Thalictrum 6, Ranunculus 29, Myosurus 2, Pæonia 1, Caltha 3, Trollius 1, Coptis 2, Aquilegia 2, Delphinium 5, Aconitum 2, Hydrastis 1, Actæa 2, Cimicifuga 1, Trautvetteria 1.—Geology and geological work in the Old World in their relation to Canada, by Principal Dawson, C.M.G., LL.D., F.R.S.—The Taconic question in geology, part 2, by T. Sterry Hunt, LL.D., F.R.S. The writer having given in the *Transactions* of the Royal Society of Canada for 1883 the first part of this paper, it remains in the second and last part to show, in the first place, more fully than has yet been done, the relations of the Taconian or Lower Taconic series of stratified rocks to the succeeding Cambrian or Upper Taconic, which some geologists have confounded with the Taconian. In this connection is given a critical discussion of the studies of Perry, Marcou, and others, and the opinions of Dana as regards the Cambrian of the Appalachian region of North America. In the second place is considered the probable equivalence of the Taconian to the Itacolumite series of Brazil and to similar rocks elsewhere in South America and the West Indian Islands, as well as in Hindostan and Southern Europe. All of these comparative studies, it is said, tend to establish the distinctness of the Taconian as a great and widely-spread series of crystalline stratified rocks occupying a horizon between the Cambrian and Montalban or younger gneiss series of Europe and North America.—Note on the occurrence of certain butterflies in Canada, by W. Saunders, London, Ontario. *Papilio cresphontes*, once a rare butterfly in Ontario, is now widely disseminated throughout that province. In the Southern United States its larvæ feed on the leaves of the orange and lemon, but in Canada they appear to thrive upon the foliage of such members of the *Rutaceæ* as *Xanthoxylon*, *Ptelea*, *Ruta*, and *Dictamnus*. *Papilio philenor* is also extremely rare in Canada, but a large flock of this species was observed by the Rev. C. J. S. Bethune near Woodstock, Ontario, in 1858. The writer also recorded the capture of *Terias mexicana* and *Thecla smilacis* at Point Pelée, Ontario, in 1882, and concluded by remarking that twenty-three years ago he had taken two specimens of a new species of *Thecla* at London, Ontario, which has since been described by Mr. W. H. Edwards as *T. læta*.—On some deposits of titaniferous iron ore in the counties of Haliburton and Hastings, Ontario, by Prof. E. J. Chapman, Ph.D. This paper, after referring to the occurrence of numerous deposits of magnetic iron ore in certain zones or belts of country in the counties of Victoria, Haliburton, Peterborough, and Hastings, describes their conditions of occurrence as those of large isolated masses or "stocks," forming in some cases "sheathed stocks," or *Stockscheiders* and *Skölars* of German and Swedish miners, as in the great iron ore zone of Arendal in Norway. Whilst these stock-masses of iron ore are for the greater part quite free from titanium, one of vast size in the township of Glamorgan, and another equally large mass in Tudor, are shown to contain a considerable amount of titanium. Detailed descriptions of these are given, with analysis of the ore by the writer.—On mimetism in inorganic nature, by Prof. E. J. Chapman, Ph.D. Mimetism—as recognised in organic nature—has been regarded on the one hand as the direct result of a protecting Providence, and, on the other, as originating in minute approaches towards the imitated object, these becoming intensified in successive generations until the imitation becomes complete or reaches its extreme limit. In this paper the writer attempts to show that neither hypothesis may be absolutely correct, but that the peculiarity may be due to some occult law of "localism" by which associated forms often become impressed with mutual resemblances. In support of this view he refers to several curious cases in which certain minerals, normally and generally of very dissimilar aspect, become closely mimetic under certain local conditions, as seen in examples of quartz and zircon, pyroxene and apatite, &c., in the phosphate deposits of the Ottawa region.—A monograph of Canadian ferns, by Dr. T. J. W. Burgess and Prof. J. Maconn, M.A., F.L.S. Prof. Maconn stated that twenty years ago the total number of ferns known to occur in Canada was forty-six, while at the present time it had increased to sixty-three. In illustrating the range of the more interesting species, he particularly noticed the occurrence of *Phegopteris calcarea* in Anticosti, where he had found it in 1882, and remarked that the same plant has recently been collected by Dr. G. M. Dawson and R. Bell in the country around and to the east of the Lake of the Woods.—On geological contacts and ancient erosion in the province of New Brunswick, by Prof. L. W. Bailey, M.A., Ph.D. This paper summarises the more important and well-established lines of physical contact between the geological formations of New Brunswick, as bearing upon the relative age of the latter and the disturbances to which they have been subjected. Three well-marked breaks separating groups of widely diverse character were recognised among pre-Cambrian strata,—the supposed equivalents of Laurentian, Huronian, and possibly Montalban horizons,—a very marked one at the base of the Cambrian, and others successively between later formations to the base of the Trias. The evidence of such breaks was shown to be of various character, including discordance of dip and strike, overlap, igneous extravasations, and intermediate erosion, and the bearing of the facts determined on the physical and geological history of North-Eastern America, was briefly discussed. The granites, which constitute so marked a feature in the geology of the Acadian Provinces, were described as intrusive, and as the cause of the extensive alteration exhibited by the formation, which they have invaded. The erosion which accompanied or followed upon the disturbances described was shown to have been enormous.—Illustrations of the fauna of the St. John group. Part III. Conocoryphidæ, with notes on the Paradoxidæ, by G. F. Matthew. The species of *Conocoryphe* referred to and illustrated are *C. matthewi*, Hartt, with three varieties; *C. elegans*, Hartt; *C. baileyi*, Hartt, with two varieties, and a new form which the author describes as *C. walcotti*. Critical remarks are also made upon *Paradoxides lamellatus*, Hartt, and *P. acadicus*.—The Glacial deposits in the neighbourhood of the Bow and Belly Rivers, by Dr. G. M. Dawson, A.R.S.M.—On the geology and economic minerals of Hudson's Bay and Northern Canada, by Robert Bell, M.D., LL.D., Assistant Director of the Geological Survey of Canada. By Northern Canada the author meant the whole of the Dominion northward of the organised Provinces and Districts, as far as known. His information was derived from his own observations around Hudson's Bay and in

the North-West Territories, and from the reports and maps of the scientific men who had accompanied the various Arctic expeditions by sea and land. Specimens and interesting notes on the geology of Great Slave Lake had been received from Capt. H. P. Dawson, R.A., who had spent last year there in charge of the Canadian Station of the Circumpolar Commission. The distribution of the various formations from the oldest to the newest was illustrated by a large geologically-coloured map of the whole Dominion. Referring first to the Laurentian system, Prof. Bell showed that it forms the surface-rock over an enormous area of circular form on the main continent, and that the central part is occupied by the waters of Hudson's Bay, which are surrounded by a border of Palæozoic rocks. If we included the Laurentian rocks of Greenland and the Atlantic coast from Newfoundland to Georgia, it would be observed that their general outline corresponds with that of the continent, which has been built up around this ancient nucleus. The Huronian strata, which constitute the principal metalliferous series in Canada, were closely associated with the Laurentian, and appeared to be always conformable with them. The largest and best-known areas were between Lake Huron and James's Bay, but Dr. Bell had found four belts of them on the east coast of Hudson's Bay, and others had been recognised in the primitive region to the west of it. Indeed wherever the older crystalline rocks had been explored in Canada, belts having the character of the Huronian series had been met with. Limestones, slates, and quartzites, interstratified with amygdaloids, basalts, &c., corresponding with the Nipigon formation of Lakes Superior and Nipigon were largely developed on the Eastmain coast and adjacent islands of Hudson's Bay, and apparently also on the Coppermine River and to the westward of it. But a set of hard red siliceous conglomerates and sandstones were seen to come between the Huronian and the Nipigon series at Richmond Gulf on the Eastmain coast, which appeared to be unconformable to both. Mr. Cochrane and Dr. Bell had found similar rocks on Athabasca Lake, Capt. Dawson, R.A., on Great Slave Lake, and Sir John Richardson to the north-east of Great Bear Lake. The conglomerates, slates, and gray argillaceous quartzites of Churchill and the white fine-grained quartzite of Marble Island were probably of this horizon. Silurian rocks were well known to be widely spread on some of the largest of the Arctic islands, and along the most northern channels of the Polar Sea. They formed an irregular and interrupted border on the western side of Hudson's and James's Bays. A large basin of Devonian strata, containing gypsum and clay-ironstone, extended southward from James's Bay. West of the great Laurentian area, Devonian rocks could be traced here and there all the way from Minnesota to the mouth of the Mackenzie River. They were not, however, so widely distributed as had been supposed by the older travellers, who had passed rapidly through the country in the early part of the century, when the whole subject of American geology was in its infancy. The so-called bituminous shale of Sir John Richardson and others, so prevalent along the Athabasca and Mackenzie Rivers, was found by Prof. Bell to consist of soft Cretaceous strata, saturated and blackened by the petroleum rising out of the underlying Devonian rocks, which here, as in Ontario, Ohio, and Pennsylvania, are rich in this substance. The principal features and the geographical distribution of the Carboniferous, Liassic, Cretaceous, and Tertiary rocks of the northern regions were next described. Among other points of interest in reference to the post-Tertiary period, Dr. Bell mentioned that the remains of both the mastodon and mammoth had been found on Hudson's Bay, and that there were reports of the occurrence of elephants' tusks on an island in its northern part. Isolated discoveries of elephantine remains had been made in the North-West Territories and several on the Rat River, a tributary of the Youkon, near the borders of Alaska. In referring to the economic minerals, Prof. Bell said that even the coarser ones, such as granite, limestone, cement-stone, slate, flagstones, gypsum, clays, marls, ochres, sand for glass-making, moulding, &c., would yet have their value in different parts of the great region under consideration. Soapstone, mica, plumbago, asbestos, chromic iron, phosphate of lime, salt, pyrites, &c., had been noted in different localities. Among ornamental stones known to occur, might be mentioned the rare and beautiful mineral lazulite discovered by Dr. Bell at Churchill, also malachite, jade, agate, cornelian, chrysoprase, &c. Lignites of various qualities, some being very good, were found in many places throughout the great tract occupied by the Cretaceous and Tertiary rocks of the Athabasca-Mackenzie Valley and on the coasts and islands of the Arctic Sea; also in Tertiary strata at Cumberland Bay and in Greenland, on the opposite side of Davis' Strait. The lignites found by Dr. Bell on the Albany and Moore Rivers were of post-Tertiary age. Anthracite of fine quality had been found on Long Island in Hudson's Bay. True bituminous coal had been reported to occur on Banks' Land, Melville, and Bathurst Islands. Petroleum, which proceeded from Devonian strata as elsewhere in North America, was very abundant along the Athabasca and Mackenzie Rivers, and vast quantities of asphalt resulting from the drying up of the exuding petroleum were found on the Athabasca, around Great Slave Lake, and at various places in the interior. In reference to the metals, the ores of iron were abundant. Inexhaustible quantities of rich manganiferous carbonate of iron existed on the islands of the Manitounik chain. It lay in beds upon the surface over hundreds of square miles, and was broken up by the frost into pieces of convenient sizes for shipping. Valuable deposits of magnetic iron had been found on Athabasca and Knee Lakes, and a great bed of pure clay-ironstone on the Mattogomi River. Capt. Dawson had found a vein of specular iron on Great Slave Lake. Copper ore had been met with on Hudson's Bay and near Lake Mistassini, and large quantities of the native metal were known to occur on the Coppermine River. A band of limestone, running from Little Whale River to Richmond Gulf, was rich in galena. Zinc, molybdenum, and manganese had been found on Hudson's Bay, and antimony in the north. Both gold and silver had been detected in veins on the Eastmain coast, and alluvial gold had been washed out of the gravel and sand of the streams among the mountains in the tract to the west of the lower part of the Mackenzie River, which Dr. Bell thought might yet become the great gold and silver region of the north, corresponding with Colorado and Nevada to the south. The fine gold-dust found in the drift in one section of the North Saskatchewan may have been derived, during the Glacial period, from the upper valleys of the Liard, on one of which the famous Cassiar gold district is situated; although Dr. Bell had some years ago originated the theory that this gold might have come from Huronian rocks in the district to the north-eastward of Edmonton.—"Note sur certains dépôts aurifères de la Beauce," by the Rev. Prof. Laflamme, D.D.—"Découverte de l'émeraude au Saguenay," by the same. — Description of a supposed new Ammonite from the Upper Cretaceous rocks of Fort St. John on the Peace River, by Prof. J. F. Whiteaves, F.G.S., &c.; On a new Decapod Crustacean from the Pierre Shales of Highwood River, N.W.T., by the same. The Ammonite referred to in the first of these communications appears to be a previously undescribed species of *Prionocyclus*, closely allied to the type of that genus, the *Ammonites woolgari* of Sowerby, but with much more closely coiled volutions. It occurs in flattened nodules, in shales which are believed to be the equivalents of the Fort Benton group of the Upper Missouri section. The Decapod Crustacean from Highwood River, a tributary of the Bow, is doubtfully referred to the genus *Hoploparia* of McCoy.—Notes on the manganese ores of Nova Scotia, by E. Gilpin, M.A., F.G.S.—A revision of the geology of Antigonish County, Nova Scotia, by the Rev. D. Honeyman, D.C.L. —"Notes sur la constitution géologique de l'Apatite Canadienne," by S. Obalski.

THE RAINS AND THE RECENT VOLCANIC ERUPTIONS[1]

THE rains this year have been more persistent than usual. At Perpignan they have been extraordinary. Is it necessary to see any relation between this circumstance and the recent volcanic eruptions? The beautiful crepuscular colorations of the past autumn and winter have been attributed to these eruptions; ought we also to attribute to them the extraordinary spring rains? I should be inclined to believe it. It is acknowledged that the presence in the atmosphere of solid particles facilitates the condensation of vapour. This would be in conformity with the position maintained by Mr. Aitken in his paper on Dust, Fog, and Clouds (volume for 1880-81, *Trans. R.S.E.*). He concludes thus:—"In an atmosphere saturated with vapour, but free from dust, there is formed neither cloud nor fog; whenever the vapour of water is condensed in the atmosphere, it is owing to the presence of those solid particles, each of which becomes, so to speak, a centre of condensation, or the nucleus of a small crystal of ice."

[1] Paper read at the Paris Academy of Sciences by M. Gay, June 23.

Very often direct observation has shown the existence of these dusts in drops of rain, and this is what has happened in all parts of the world since the crepuscular colorations of 1883-84. The dusts collected have a composition which usually indicates a volcanic origin. It has been shown that other volcanic eruptions have been followed by red glows in the sky; it appears to me that it may also be shown that they have been followed by abundant rains. The eruptions which have been referred to are those of the Skaptar Joekull, in Iceland, in the beginning of May 1783; of a new volcano, since disappeared, in the Sicilian Sea early in July 1831; Cotopaxi, in America, in 1856; Vesuvius in 1862. These eruptions were followed by colorations; I add that they were followed by rains which exceeded the mean. The following, in millimetres, are the monthly heights of rain collected on the terrace of the Paris Observatory; the second line is the monthly mean of from twenty to thirty years:—

EXPERIMENTS ON THE PASSAGE OF ELECTRICITY THROUGH GASES—SKETCH OF A THEORY[1]

THE passage of electricity through gases has of late years become a very favourite subject for experimental investigation. A large number of facts have thus been accumulated, and it becomes of importance to see whether these facts throw any light on the theoretical notions which we have based on other branches of electrical inquiry.

If we have two bodies at a different electrical potential separated by a layer of air, we might imagine the air in contact with the bodies to become electrified, then move on, impelled by the electric forces, and re-establish equilibrium by giving up their charges. The passage of electricity through gases would then be similar to the diffusion of heat. But, however natural such a view would be, it is impossible to maintain it in the face of experimental facts. The experiments which I shall bring before you to-day seem to me to support, on the contrary, the idea that the passage of electricity through a gas resembles the phenomenon studied by Helmholtz under the name of electrolytic convection.

I shall avoid as much as possible all suppositions and hypotheses which cannot be put to the test of experiment; but it seems necessary to start with some assumption in order to avoid too great a vagueness in the subsequent explanations. The assumption which I shall make is this: In a gas the passage of electricity from one molecule to another is always accompanied by an interchange of the atoms composing the molecule. I shall also try to prove that many facts are easily explained by the assumption that the molecules are broken up at the negative pole.

If, in a vacuum-tube of the ordinary form, the discharge is passed at a pressure of about one millimetre, a luminosity is seen round the negative pole which is called the negative glow. A luminous tongue projects from the end of the positive pole, which I shall call the positive part of the discharge, without meaning to imply that it is charged with positive electricity. The positive part of the discharge and the negative glow are separated by a non-luminous space, which I shall call "the dark interval." The glow itself is divided into three layers, the thickness of which increases with decreasing density. Closely surrounding the electrode itself, we have in the first place a luminous layer, which on new electrodes is of a golden colour. The spectroscope shows the presence of sodium and hydrogen; the sodium is due to foreign matter deposited on the electrode, and the hydrogen is expelled by the action of the heat out of the electrode by which it had been absorbed. When the electrodes have been in use for some time, the golden colour disappears, and the spectrum belonging to the gas used is seen. The second layer is known by the name of the dark space. The third layer is the glow proper.

The theory which I shall endeavour to establish is this: That within the first layer the gaseous molecules are decomposed, that their negative parts are projected with great velocity through the dark space, that this velocity is gradually reduced by impacts within the glow, and that in the positive part of discharge the discharge takes place by diffusion except when stratifications appear.

According to the kinetic theory of gases, the molecule of mercury vapour consists of a single atom, which is incapable of vibration. Mercury has a very brilliant spectrum, which proves that the theory is incomplete in some important point. It is well known, on the other hand, that the theoretical conclusion receives support from the fact that the vapour-density of mercury vapour is anomalous. If, as is generally supposed, the molecule of the majority of gases contains two atoms, that of mercury can only contain one. If an essential part of the glow discharge is due to the breaking up of the molecules, we might expect mercury vapour to present other and much simpler phenomena than the gases with which we are generally accustomed to work. *This, indeed, is the case; for I find that, if the mercury vapour is sufficiently free from air, the discharge through it shows no negative glow, no dark spaces, and no stratifications.* At the ordinary temperature the spark does not pass through mercury vapour; but if a tube free of air, but containing mercury vapour, is heated, the discharge passes always in a continuous stream of light. It is not always quite symmetrical with respect to the two poles; and a very curious tendency of the spark is noticed, to pass at the negative pole rather from the glass out of which the electrode protrudes than from the metallic electrode itself. A brilliant sodium spectrum then appears at the point from which the spark sets out. Whenever small traces of air remain, stratifications are very apt to appear, as a mixture of air and mercury gives fine stratifications, but I have never noticed them after sufficient removal of the air.

I now pass to the description of an experiment which seems to me to be only capable of explanation by the views brought forward in this paper, and I should like therefore to consider them as crucial experiments, which have to be explained by any true theory of the discharge. As negative electrode, I use an aluminium cylinder of 5·5 cm. internal diameter and 8 cm. long. A long aluminium wire running parallel to the axis of the cylinder at a distance of about an inch formed the positive electrode. On exhaustion, the discharge at first passes as a spark in the ordinary way, but as the pressure decreases the glow gradually surrounds the whole cylinder, *with the exception of a dark strip about 2 or 3 cm. in width, directly opposite the positive wire.* The positive electrode seems, therefore, to repel the negative glow.

The following seems to me a plausible explanation of the phenomenon which I have just described. The rapid fall of potential which is observed on crossing the negative electrode suggests at once, independently of any theory that we have to deal with, the action of a condenser, for we know that no statical charge can produce a finite difference of potential at the electrode, while a double layer will produce a discontinuity. Although it may not be proved that an absolute discontinuity of potential exists at the kathode, it is yet certain that a very rapid fall occurs at that place. This is all that is necessary for the argument.

We recognise such a double layer in the case of electrolytes, but there is an essential difference in the thickness of the layer within which we must imagine that condenser action to take place. In the liquids that thickness must be very small, as is shown by the intensity of the observed polarisation currents. The positively electrified matter in every case is kept against the negative surface by a joint action of electrical and chemical forces, for it has been shown by Helmholtz that only thus can we explain a difference of potential between two bodies. It is the chemical forces which keep the electricities asunder. The gaseous molecules or atoms, however subject to their mutual encounters, and always having certain velocities, will tend to leave the surface. They are kept near the surface, however, by the electrical forces.

Suppose, now, that a positive electrode is placed near such a condenser. The resistance of the gas is so much greater than that of the metal electrode that we shall assume the whole elec-

[1] Abstract of the Bakerian Lecture. Read before the Royal Society, June 19, 1884, by Arthur Schuster, Ph.D., F.R.S.

trode to be of the same potential. The lines of force will then cut the surface at right angles, and could we assume the condenser to be infinitely thin, there would only be a normal force acting on its particles; but as the lines of force are curved, the particles not in immediate contact with the surface are acted on by a tangential force which will tend to drive them away from the positive electrode. As a steady state will only be possible when the total force is normal throughout the condenser, we arrive at the condition for the steady state that within the condenser the fall of potential must be the same for equal distances measured along the normal to the surface.

Experimental evidence speaks strongly in favour of such a conclusion. If, for instance, a thin wire is used as electrode, it is well known that the tension at the end of the wire before discharge is very much larger than anywhere else. At high pressures the discharge passes indeed from the end of the wire, but as the exhaustion proceeds, the glow gradually covers the whole wire, and the same amount of electricity flows out of equal areas situated anywhere on the wire, for the dark space which alters its width with the intensity of current is everywhere the same; this implies that the fall of potential per unit distance is the same all over the wire.

Hitherto we have only assumed a certain number of particles positively electrified in the immediate neighbourhood of the negative electrode, and we have left it altogether undecided what these particles are. But if we consider now the fact that the glow does not appear opposite the positive electrode, that is to say, that while the fall of potential is the same all over the surface the flow is stronger at some places than at others, we are driven to the conclusion that the flow does not altogether depend on the fall of potential, and we must again look for an explanation in the chemical as well as the electric forces. Wherever the fall of potential is chiefly produced by the presence of the positively electrified particles, which I now assume to be the decomposed molecules of the gas, these will help by their chemical action to decompose other molecules. Opposite the positive pole the fall of potential is principally due to nearness of that electrode; chemical forces are absent, and the molecules will not be decomposed. This is, I believe, the explanation of the dark area. And it brings with it the explanation of a large quantity of other facts, as, for instance, the one which has been so long observed and well established, that once a current is set up in the gas it requires a much smaller electromotive force to keep it going. For the discharge, according to us, will generally be introduced by a spark which must give the first supply of decomposed molecules before the continuous glow discharge can establish itself.

I may for the sake of clearness once more mention shortly the principal points of the argument.

The rapid fall of potential in the neighbourhood of the negative electrode renders the presence of positively electrified particles in its neighbourhood necessary.

If the distance through which the condenser action takes place is sensible, the positively electrified particles will be acted upon by a neighbouring positive electrode.

A steady state will be established in which the fall of potential along the normal from the surface will be everywhere the same.

As however the flow is stronger away from the positive electrode, we must conclude that other forces besides electrical forces determine the flow.

It is natural to assume that these are chemical forces: that, in other words, the positively electrified particles are the decomposed molecules, which by their presence assist the decomposition of others, and therefore the formation of the current.

Unless a flaw is detected in this line of argument, I think that the conclusion must be granted, namely, that the decomposition of the molecules at the negative electrode is essential to the formation of the glow discharge. This is really all that I endeavour to support in this paper. The rest can only be settled by further experiments. And amongst the rest I count also the primary cause which originally produces the decomposition of molecules at one pole rather than at another. It is possibly due to an electromotive force of contact between the gas and the electrodes which tends to make the gas electronegative.

The gaseous molecules, then, according to our theory, are decomposed at the negative pole. Their negative constituents can follow the electric action, and as the fall of potential in the immediate neighbourhood of the pole is very rapid, the atoms will leave the pole with considerable velocity. That the region of the dark space is filled with matter projected from the negative pole follows almost conclusively from the experiments of Goldstein and Crookes, and is also shown in a most striking way by an experiment due to Hittorf. If a tube contains two parallel wire electrodes at a distance of say a quarter of an inch, the discharge will at high pressure pass in the usual way from electrode to electrode, but at very low pressures the discharge from the positive pole goes away from the negative. The results can be shortly expressed by saying that, as far as the positive pole is concerned, the inner boundary of the dark space forms the negative electrode. If the dark space is small and does not reach to the positive pole, the discharge passes from the latter towards the negative pole, but as soon as the dark space extends beyond the positive pole, the positive part of the discharge goes towards the nearest point of the dark space that is straight away from the negative pole.

We have then two closely adjoining, almost overlapping parts, in which the discharge is in opposite directions, and this could not be unless electricity is carried by matter which can, owing to its inertia and high velocity, move against the electric forces. To my mind this experiment proves conclusively that the negative electricity is bound to matter projected with high velocity away from the negative pole.

Goldstein has shown that when a thin pencil of the negative glow belonging to one electrode passes close to another the pencil is deflected. According to our view, such a pencil would be formed by a succession of negatively charged particles projected in nearly the same direction away from the negative electrode; as these particles pass by another kathode, they are naturally deflected out of their path by the electric forces. Goldstein has shown that if the current is equally divided between the two kathodes, the deflection is independent of the intensity of the current, the pressure, and the nature of the gas. This is exactly what ought to happen according to our theory, for strengthening the current at one kathode means, as will presently appear, increasing the velocity of the particles. The square of the velocity will increase in the same ratio as the total fall of potential in the neighbourhood of the negative pole; as the particles pass the other kathode, the forces from it are increased in the same ratio as the square of the velocity with which they are moving, and consequently the path will remain the same. Similarly all the other experimental facts established by Goldstein can be easily explained.

The most conclusive proof of the view adopted in this paper would be found in the demonstration that the amount of electricity carried by each particle was always the same, whatever the current. I propose to test this fact in the following way:—It was found by Hittorf that the particles proceeding from the negative electrode, and projected at right angles to the lines of force in a magnetic field are bent round in a circle. This is as it should be, and I calculate that the radius of the circle ought to vary as $\sqrt{F/e}$, where F is the total fall of potential within the region in which the particles acquire their velocity, and e is the amount of electricity carried by each particle. As the current increases, it is shown by Hittorf that F increases; and I find that at the same time the diameter of the ring in the magnetic field increases. If this diameter varies as the square root of F, it would be proved that e must be constant as it is in electrolysis. At present we can only say that the average amount of electricity carried by the particles must increase less rapidly than the fall of potential. If e varies at all, we should expect it to vary proportionally to the fall of potential in the neighbourhood of the negative electrode, and in that case the diameter of the ring would be independent of the current, which it is not.

The theory which I advocate involves the existence of a polarisation, and it might be considered a difficulty that no polarisation currents have with certainty been observed in gases. I believe the difficulty only to be apparent, for the experiments prove that the fall of potential near the negative pole, though rapid, is not sudden, so that the layer within which the condenser action takes place is very much thicker in gases than in liquids. The capacity of the condenser is therefore smaller, and though the total fall of potential in the gas may even be stronger than in the liquid, the polarisation currents might escape observation.

With regard to the positive part of the discharge it will be sufficient here to mention that stratifications are principally observed in mixtures of gases or in compound gases, and that in

the intervals between two stratifications the discharge is very likely carried as through the dark space at the negative electrode, while in the stratifications recombination of the decomposed atoms takes place.

An interesting law has been proved by Hittorf and E. Wiedemann in the case of the unstratified discharge. Hittorf shows that the fall of potential is the same in the positive part for the same tube whatever the current. This means that the energy dissipated is proportional to the current, and not to the square of the current as in a liquid. In the latter form the proposition had previously been proved by E. Wiedemann, who has shown that the total quantity of heat generated is proportional to the total quantity of electricity which has passed through the tube, whether in a few strong sparks or many weaker ones.

These experiments seem to point to the fact that once the original velocity of the particles at the regular pole has been reduced the velocity becomes independent of the strength of the current, that is to say, that in the positive part of the current greater intensity only means a greater number of particles taking place in the discharge.

The paper also contains spectroscopic evidence as to the state of dissociation in a vacuum tube, especially in the negative glow.

The question as to how the electricity passes from the electrode to the gas is not discussed, nor is it possible at present to decide, should the theory prove true, whether the polarity of the atoms in the molecule depends on the way in which these are combined, or whether that atom takes positive polarity which happens to be nearest the negative electrode as the molecule approaches it.

In conclusion some novel influence of the magnet on the negative glow is described, and it is shown that two different effects have to be clearly distinguished. The first is an effect of the magnet on the discharge when that discharge is established, and has been sufficiently well investigated. But the second effect depends on the question from what part of the negative electrode the discharge sets out. With respect to this question we meet with many contradictory and inaccurate statements. If at any place the magnet tends to throw the glow together the temperature will be raised, and owing to this fact the current will be strengthened, which again raises the temperature. It may thus happen that a slight cause can induce the current to pass almost exclusively from one part of the negative electrode. For a detailed description the reader is referred to the paper itself and the illustrations accompanying it.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

MR. ANDREW GRAY, M.A., assistant to Sir William Thomson in the Natural Philosophy department of the University of Glasgow, has been appointed to the Chair of Physics in North Wales University College. Dr. J. J. Dobbie, M.A., formerly "Clark" Fellow in Natural Science, has been elected to the Chair of Chemistry and Geology.

THE following is a list of prizes, scholarships, associateships, &c., awarded at the Normal School of Science and Royal School of Mines, South Kensington, June 1884:—First Year Scholarships: Albert G. Hadcock; Fred. Carrodus; William C. Rowden; Thomas Rose. Second Year Scholarships:—George Gibbens; Isaac T. Walls. "Edward Forbes" Medal and prize of books for biology, Thomas Johnson; "Murchison" Medal and prize of books for geology, Martin F. Woodward; "Tyndall" prize of books for physics, course 1, Isaac T. Walls; "De la Beche" Medal for mining, Herbert W. Hughes; "Bessemer" Medal, with prize of books from Prof. Chandler Roberts for metallurgy, (1) Percy Bosworth-Smith, (2) William F. Grace; "Hodgkinson" prizes for chemistry, (1st, books, &c.) George T. Holloway; (2nd) Stephen J. Elliott and William P. Wynne. Associateships in Normal School of Science: chemistry, 1st class, George T. Holloway, William P. Wynne, and Elizabeth Healey; physics, 1st class, Benjamin Illingworth and Alfred Howard; biology, 2nd class, and geology 2nd class, Joseph Lomas. Associateships in Royal School of Mines: mining, 1st class, Herbert W. Hughes; mining, 2nd class, and metallurgy, 1st class, George H. Schröder; metallurgy, 1st class, Percy Bosworth-Smith, Alfred Sutton, Henry G. Graves, and Harry J. Chaney; metallurgy, 2nd class, William F. Fremersdorf and Erskine H. B. Stephenson.

SCIENTIFIC SERIALS

American Journal of Science, June.—On the tendency of rivers flowing to the north or to the south to encroach on their east or west banks respectively, by G. K. Gilbert. The author, after further study, here finally adopts the view that this tendency is sufficiently accounted for by terrestrial rotation.—Examination of Mr. Alfred R. Wallace's "Modification of the Physical Theory of Secular Changes of Climate," part ii., geological and palæontological facts in relation to Mr. Wallace's modification of the theory, by Dr. James Croll.—Description of a new fossil marsupial from the Miocene deposits of Chalk Bluffs, Colorado, by W. B. Scott. This opossum, which the author names *Didelphys pygmæa*, is intermediate in size between the *D. murina* and *D. elegans* of South America. It establishes the fact that the small insectivorous opossums now characteristic of South America existed in Miocene times in North America, and is additional evidence that the latter continent is the source from which the former received the greater part of its fauna.—On a method of obtaining autographic records of the free vibrations of a tuning-fork, and on the autographic recording of beats (five illustrations), by Alfred G. Compton.—Notes on the volcanic rocks of the Great Basin, stretching for over 400 miles from the Sierra Nevada eastwards to the western base of the Wahsatch Range, by Arnold Hague and Joseph P. Iddings. In this region the association of andesites and trachytes, or trachytes and rhyolites, is unknown, and the authors infer that trachytes occupy a far more restricted position among volcanic rocks than has hitherto been generally supposed. They also consider that the geological independence of rhyolite and trachyte is now clearly established.—Transition from the copper-bearing series to the Potsdam in the St. Croix River Basin, Wisconsin, by L. C. Wooster.—On the expression of electrical resistance in terms of a velocity, by Francis E. Nipher.—Lateral astronomical refraction, by J. M. Schaeberle. The author proposes a simple remedy for the errors in astronomical observations arising from the assumption that all atmospheric layers of the same density over any given locality are parallel to the horizon.—Description of a remarkable variety of kaolinite from the National Belle Mine, Red Mountain, Ouray County, Colorado (three illustrations), by Richard C. Hills.—The influence of convection on glaciation, by Geo. F. Becker.—Description of a new Dinichthys (*D. minor*) from the Portage Group of Western New York (two illustrations), by Eugene K. S. Ringueberg. This specimen differs in several important respects from the two Ohio species *D. Herzeri* and *D. Terrelli*, Newb.—Mineralogical notes on allanite, apatite, and tysonite (two illustrations), by Edward S. Dana.

Revue d'Anthropologie, tome vii. fasc. 2, Paris, 1884.—On the weight of the cerebellum and the hemispheres according to Broca's mode of registration, by Dr. Philippe Rey, who has been commissioned by M. Topinard to continue the comparative tables and determinations which had already served as the basis of the memoir drawn up by the latter on the weight of the brain. Bicêtre, Saint-Antoine, La Pitié, and La Salpêtrière are the sources whence Dr. Rey has derived the requisite data for his work, and his conclusions must therefore be regarded as having more of a special than a general interest, since they are exclusively based on observations of the particular classes of persons confined in these institutions.—Study of primitive peoples, as the Kaffirs, and more especially the Zulus, by Élie Reclus. This paper presents little interest or novelty for English readers, as it consists almost entirely of extracts from English travellers and missionaries, and neither opens up new sources of information nor throws any novel light on the ethnography of the nations of whom it principally treats.—On the Kalmuks, by M. Deniker. In this second part of his memoir the author, after completing his description of the anatomical and physiological characters of the Kalmuk race, which he shows to be generally brachycephalic, supplies much important information regarding their present social and political condition under the influence of Russian domination. It would appear that the people have considerable mental capacity, various young Kalmuks having taken good places in the examinations of the University of Astrakan, and officiating creditably as medical practitioners, and as directors of the hospitals which the Russians are establishing for the benefit of the tribes. The change from a nomadic to a stationary life seems, however, to have been productive of decided injury, the census of 1869 howing a diminution of 22 per cent. in the population since 1862. According to the author, this diminution principally affects females, while this census presents, moreover, the singular

feature that male births are in excess of those of the opposite sex in the proportion of 139 to 100. It is conjectured, however, that this estimate may be incorrect, and due to the fact that women and female children are regarded as of little importance, on which account their numbers may not always be taken with exactitude. There would, on the other hand, appear to be no doubt of the fatal influences on the Mogul of the change from an easy, inactive, nomad life to that followed in a settled community, in which the struggle for existence has to be carried on under the pressure of continuous if not hard labour and fixed regulations.—On the so-called "xyphoid" angle, by M. Charpy. By this term the author designates the angle comprised between the edges of the xyphoid depression of the thorax, while his paper is devoted to the consideration of the extent to which its general inferiority in women may be due to the pressure exerted by corsets, and how far it depends on physiological causes and pathological conditions.

Bulletins de la Société d'Anthropologie de Paris, tome vii. fasc. 1, 1884.—This number, as is usual with the first of the series for the year, gives the various rules and reports of the Society, with a list of its members and associates, and the presentations made to it in the preceding year, together with the opening address of the president, M. Hamy. The remaining contents are:—A report, by M. de Mortillet, of the finds at Marcilly-sur-Eure, between Dreux and Évreux, where, in a red argillaceous loam, laid bare by a railway cutting, a cranium has been discovered of the Neanderthal type. Near the spot are deposits containing elephant, rhinoceros, and other bones, intermingled with numerous flint splinters.—On the Celtic cemetery of the island of Thinie at Portivy, Saint-Pierre-Quileron, by M. Gaillard. In 14 of the 27 stone cists of various sizes which have escaped the destructive encroachments of the sea numerous remains have been found, some containing four bodies laid one above the other, and generally in inverse directions, and much bent. Some of the lower skeletons are admirably preserved, and all are remarkable for an extraordinary development of the occipital region and great flatness of the tibia. Flints and potsherds of the Dolmen age occur in large numbers.—On the Quaternary Equidæ, by M. André Sanson, who bases his observations on the large collection of bones found by M. Chauvet in the Charente and Dordogne.—On the supposed flint *atelier* of Moulin-de-Vent, Charente-Inférieure, by M. Léon Rejou. According to M. Rejou, we have here not only the site of a prehistoric factory of ordinary flint implements, but the spot at which was manufactured a special form of these instruments, found here in considerable numbers, which he compares to our modern gimlet, and of which he has failed to discover any specimens either in the neighbouring Robenhausian deposits, or at any of the other French flint stations.—On the prehistoric flint beds at Chelles, by M. D'Acy. The most recent finds include a molar of *Elephas primigenius*, which thus confirm the hitherto contested view that this mammoth form must be included in the fauna of the Chelles beds, from which M. Gaudry had moreover already obtained three similar teeth.—On the so-called "Viens-Viens" of St. Domingo, by Dr. Dehoux, who believes that these, and other wild tribes of the Antilles, are the degraded representatives of mixed breeds, and not the descendants of primitive Indians.—On a placental anomaly, by Dr. E. Verrier, with illustrations of several other analogous abnormalities suggestive of the influence of atavism in the human subject.—On the races of the Philippine Islands, by Dr. Montano, with anthropometric tables. The author discovered traces both in ancient and recent skulls of the artificial cutting away of parts of the teeth practised in the archipelago, but he has not met in the living subject with evidence of the maxillary and other lesions, believed, according to various authorities, to result from this practice.—On a case of scaphocephalus observed in the living subject, by Dr. Delisle, with comparative tables.—On the Toltecs and their migrations, by M. Charnay.—On the Botocudos and Purys of the forests of Rio Janeiro, by Dr. P. Rey, with a vocabulary of their commonest words.—Contributions towards the ethnography of the Fuegians, by Dr. Hyades, member of the French Mission to Cape Horn. This paper is supplemented by a vocabulary and grammar drawn up by Mr. Bridges of the South American Missionary Society, whose papers on the manners and customs of the Fuegians from "A Voice for South America," vol. xiii. 1866, is also given *in extenso* by the author.—On the use of iron in Egypt, by M. Soldi; and on the antiquity of the knowledge and use of this metal by the Egyptians, by M. Beauregard. In the former of these papers the author attempts to show that stone implements were generally used in the preliminary labour of cutting blocks for statuary, and iron tools only for completing the final processes of sculpture. M. Beauregard, in his paper, deals, on the other hand, with the chronological bearings of the question, and considers at length the precise meaning of the various hieroglyphics supposed to indicate this metal.—On the rational and methodic process of deducing proportional means, more especially in reference to the general mortality of France, by Dr. Arthur Chervin. The author explains the methods employed by him for the categorical grouping of diseases as shown in his "Géographie médicale de la France."

Sitzungsberichte der Naturforschenden Gesellschaft, Leipzig, 1883.—In a paper on the "Petrographic composition and structural relations of the Leipzig Graywacke," Dr. Saur confirmed the previous conclusion of Geinitz, that the rocks cropping out in the diluvial of the Leipzig district belong to the North Saxon Graywacke system, which appears to be partly Cambrian, partly Lower Silurian.—A comprehensive memoir on the German slugs was read by Dr. Simroth, who divided this family into two groups: ARION, with three species (*hortensis*, *subfuscus*, and *empiricorum*); and LIMAX, with four subdivisions (*Limax* proper, *L. lævis*, *L. agrestis*, and *Amalia*). In a second memoir the author dealt specially with the question of hermaphroditism and differentiation of sex in *Limax lævis*.—A paper on the development of the tissues and histological system of the mammalians, by Prof. Rauber, recognises two fundamental types with possible transitional forms: (1) the type characterised by invagination of the embryoplastic pole of the germ cell (mouse, rat, guinea-pig); (2) the more general type marked by absence of invagination.—In an essay on the northern Silurian erratic boulders of the Leipzig district, Dr. Felix traces these rocks ultimately to South Sweden, Bornholm, Gotland, and especially Schonen.—A recent visit to the Brunswick Anatomical Museum suggests some interesting remarks to Dr. Hennig on the subject of malformations of the female pelvis in early life.—A paper by Dr. Rauber, on the influence of temperature, atmospheric temperature, and various elementary substances on the development of the animal ovum, aims especially at a more exact knowledge of the inner properties of the embryo. The subject is treated under two heads: (1) the power possessed by germs in various stages of resisting outward influences; (2) their plastic capacity, or power of adapting themselves by changes and modifications of all sorts to changed outward conditions. In a second paper the author reports the results of researches on the influence of increased or diminished proportions of saline solutions on Mollusks, Crustacea, Hydræ, and other aquatic fauna. His experiments point at the conclusion that the primæval oceanic waters must have always been saline.—In a memoir on the tin ores of the Eibenstock granitic system and their origin, Dr. Schröder infers that the tin ores resting on the turmaline granites of Eibenstock have been exposed by the weathering of the associated rocks. The same conclusion is arrived at by Dr. F. Schalch respecting a new variety of strontianite discovered at Wildenau, near Schwarzenberg, in the Erzgebirge.—Some remarks on the traces of glacial action on the porphyry rocks of Wildschütz near Eilenburg, Saxony, were submitted by Dr. Dalmer, who pointed out that the striæ ran in two different directions, the older and normal from north-west to south-east, the more recent exceptionally between 60° N. and 80° E.—Dr. A. Sauer presented an exhaustive analysis of some specimens of the ashes from the Krakatoa eruption of last year. The material appeared to be a lava evidently of the augite-andesite family, closely related in structure to that of Turrialba in Costa Rica.—Dr. R. Sachsse reported on a new chlorophyll dye of a yellowish-brown colour, easily soluble in alcohol. The formula of this dye, which he names β-phæochlorophyll, is $C_{24}H_{23}N_3O_4$. In another paper he gave a chemical analysis of the feldspar present in the gabbro rocks of Rosswein, Saxony, which appeared to be closely allied in structure to true labradorite.

La Belgique horticole for October-December 1883 devotes a large portion of its space to a list of ornamental plants described or figured in Belgian or foreign journals, or in gardeners' catalogues, or exhibited in London, in 1882. The list comprises the large number of 251 species, of which 163 are Monocotyledons, and 105 belong to the single order of Orchideæ. The names are followed by very short descriptions.—There are also in the magazine a number of short notes of interest to floriculturists, the conclusion of an article

on the botanical discoveries of M. Roezl in America, and two fine coloured plates of *Cypripedium Spicerianum*, and *Aphelandra Margaritæ*.

SOCIETIES AND ACADEMIES

London

Royal Society, June 19.—"The Influence of Stress and Strain on the Physical Properties of Matter."[1] Part I. Moduli of Elasticity—*continued*. Relations between Moduli of Elasticity, Thermal Capacity, and other Physical Constants. By Herbert Tomlinson, B.A. Communicated by Prof. W. Grylls Adams, M.A., F.R.S.

The thermal capacity of each of the wires already used for the experiments on moduli of elasticity and electrical conductivity described in Parts I. and II. of this paper[2] was determined.

Every precaution was taken both with regard to the instruments themselves and the mode of using them to avoid error, and the formulæ given below may be received with great confidence.

Metal	Density at 20°C., density of water at 4° C. = 1	Formulæ for the number of thermal units required to raise the temperature of unit mass from 0° C. to t° C. Thermal capacity of water at 0° C. = 1.	Thermal capacity per unit mass at t° C.
Aluminium ...	2·731	·20700t + ·0001152t^2	·20700 + ·0002304t
Iron	7·759	·10601t + ·0000701t^2	·10601 + ·0001402t
German-silver.	8·632	·09411t + ·0000053t^2	·09411 + ·0000106t
Zinc	7·138	·09009t + ·0000374t^2	·09009 + ·0000748t
Copper	8·851	·09008t + ·0000324t^2	·09008 + ·0000648t
Silver	10·464	·05466t + ·0000218t^2	·05466 + ·0000436t
Tin	7·264	·05231t + ·0000361t^2	·05231 + ·0000722t
Platinum-silver	12·616	·04726t + ·0000138t^2	·04726 + ·0000276t
Platinum ...	21·309	·03108t + ·0000063t^2	·03108 + ·0000125t
Lead	11·193	·02998t + ·0000153t^2	·02998 + ·0000306t

It will be seen that the thermal capacity of all the metals examined increased with the temperature, a result which we find confirmed by the observations of other investigators.

The thermal capacities of the alloys platinum-silver and German-silver are, within the limits of error, exactly the same as those calculated from the proportions of their components. Thermal capacity is, therefore, a physical property which is not likely to be altered to any appreciable extent by small impurities, so that the results obtained by different experimenters agree very closely with each other.

It has been proved[3] that if e be taken to denote "Young's Modulus," and a the mean distance between the centres of two adjacent molecules, $e \times a^7$ is in the case of most metals approximately a constant. From this it would follow that the law of force proved by Maxwell in his experiments on the viscosity of gases[4] to exist between the molecules of a gas is approximately true for solids, accordingly the force between any two adjacent molecules of a solid is approximately as the fifth power of the distance between their centres. Now if we denote the atomic mass by A, the density by Δ, the thermal capacity per unit mass by C_m, and the thermal capacity per unit volume by C_v, we have the following relations:—

$$C_m \times A = \text{a constant};$$
$$C_v = \Delta \times C_m;$$
$$e \times a^7 = \text{a constant};$$
$$a \propto \left(\frac{A}{\Delta}\right)^{\frac{1}{3}}$$

From these relations we obtain—

$$\frac{e}{C_v^{\frac{7}{3}}} = \text{a constant};$$

or that the cube of "Young's Modulus" varies as the seventh power of the thermal capacity per unit volume. This relation was found to hold approximately not merely for the metals here examined, but also in the case of a great many substances for which the values of C_v and e have been determined by other investigators.

Still more approximately is it believed that this relation would hold good if for "Young's Modulus" the bulk-modulus of elasticity were substituted. Denoting the bulk-modulus by e_v, it was found that, within the wide limits of error to which determinations of the value of the bulk-modulus are liable to be affected—

$$\frac{e_v}{C_v^{\frac{7}{3}}} = \text{a constant}.$$

Neither of the above relations can be true for all temperatures, inasmuch as, whilst the value of e_v diminishes with rise of temperature, that of C_v increases, but at ordinary temperatures it seems that the bulk-modulus of elasticity can be calculated from the thermal capacity per unit volume by the formula—

$$e_v = 2071 \times 10^6 C_v^{\frac{7}{3}}.$$

The thermal capacity per unit volume increases with the temperature, and the researches of Matthiessen, Fizeau, and others on the one hand, and of Kohlrausch on the other, have shown that there is a like increment in the thermal expansibility and torsionability[1] of metals. A careful comparison was made of the various increments above mentioned, and it is shown in the paper that whilst the ratio of increase per unit of expansibility with rise of temperature to corresponding value in the case of torsionability[2] is, within the limits of error of observation, unity, that in which thermal expansibility and thermal capacity are concerned is about two, so that the rate at which thermal expansibility increases with the temperature is about twice the rate at which thermal capacity increases. The rate of increase of both thermal expansibility and thermal capacity varies with the nature of the metal, being greatest for iron and least for platinum.

The so-called "real thermal capacity" of a solid may be found by dividing the thermal capacity of hydrogen per unit mass at constant volume, namely, 2·417, by the atomic mass; and this part of the capacity will be independent of the temperature. If the "real capacity" be subtracted from the total thermal capacity we obtain that part of the capacity which does vary with the temperature, and which has therefore in this paper been designated the "variable thermal capacity." The following table shows that *the rate of increase per unit of thermal expansibility is at 0° C., and therefore at any temperature, equal to the increase per unit of the "variable capacity"*:—

Metal	Rate of increase per unit at 0° C. of "variable thermal capacity" = C′	Rate of increase per unit at 0° C. of thermal expansibility = E	$\frac{E}{C'}$
Iron	·00230	·00309	1·34
Tin	·00216	·00250	1·16
Aluminium ...	·00197	·00215	1·09
Lead...	·00192	·00174	0·91
Copper	·00127	·00196	1·54
Zinc	·00157	·00170	1·09
Silver	·00135	·00155	1·15
Platinum	·00064	·00061	0·95

It is shown in the paper that the thermal capacity per unit mass is nearly two and a half times the "real capacity," so that only two-fifths of the whole thermal energy which we may impart to a mass of metal goes towards raising the temperature, the remaining three-fifths being expended in internal and external work. The external work is practically insensible in ordinary cases. Of the internal work, that expended against bulk-elasticity amounts in the limiting cases from 1/1,000th to 1/10,000th of the whole, and, though greater than the external work, is almost insensible; moreover, there seems to be no relationship whatever between the whole thermal capacity per unit volume and the work done against bulk-elasticity.

Raoul Pictet has concluded[3] that the amplitude of the oscillation of molecules around their positions of equilibrium may be taken as corresponding to temperature, and in the case of several metals has shown that

$$T \times \beta \times a = \text{a constant},$$

[1] The original title of the paper has been altered to the above, as being more exact in expression.

[4] *Phil. Trans.* 1866, vol. cxxvi. part i.

[1] The inverse of "simple rigidity."
[2] Iron and copper are the only two metals for which the increase of torsionability with rise of temperature has been examined.
[3] NATURE, 1870, p. 356.

where T is the melting-point temperature reckoned from absolute zero, β the coefficient of linear expansion, and a proportional to the distance between the centres of adjacent molecules. From the above relation, combined with those already mentioned, we deduce

$$\frac{T \times \beta}{C_v A} = \text{a constant};$$

and

$$\frac{T \times \beta}{e_v A} = \text{a constant}.$$

The first of these two relations was found to hold good for ten out of twelve metals examined, but for the metals bismuth and antimony the ratio $T\beta : C_v A$ is almost exactly *one-half* of the ratio obtained for the other metals. It was concluded that for most metals the melting-point temperature may be approximately calculated from the formula—

$$T = \cdot 02253 \times \frac{C_v A}{\beta}.$$

Where C_v and β represent the mean thermal capacity per unit volume, and coefficient of expansion respectively between 0° C. and 100° C.

The second of the two relations was found also to approximately hold good.

In the paper will be found a full discussion of the experiments of Joule[1] and Edlund[2] on the thermal effects produced by mechanical stress in metals.

According to the researches of the latter the *observed* thermal effects of longitudinal stress on a wire is to be found by dividing the *theoretical* thermal effects by 1·61, since part of the work expended on a wire which is stressed longitudinally finds its equivalent in molecular effects which are not thermal. This view seems to be partly supported by some experiments made by the author on the viscosity of metals.

Zoological Society, June 17.—Prof. W. H. Flower, President, in the chair.—Mr. H. Seebohm exhibited and made remarks on some specimens of rare Asiatic and European birds, and called special attention to examples of a newly-discovered Russian species, *Bonasa griseiventris* (Menzbier).—Mr. Sclater exhibited the knob of the culmen of the beak of a Rough-billed Pelican (*Pelecanus*), which had been shed by the bird in the Society's Gardens last autumn; and called attention to the fact that on coming into breeding plumage again this summer the bird had grown another knob.—Mr. Sclater also called the attention of the meeting to a very singular habit of a Vasa Parrot (*Coracopsis vasa*), as observed in the Society's Gardens.—Mr. F. Holmwood gave an account of his observations on the employment of the *Remora* by native fishermen of Zanzibar for the purpose of catching turtle and large fishes.—Mr. R. Bowdler Sharpe read some further notes on the new Corsican Nuthatch (*Sitta whiteheadi*), in continuation of former communications on the same subject.—A communication was read from Dr. G. Hartlaub, in which he gave the description of a new species of Creeper of the genus *Salpornis*, discovered in Eastern Equatorial Africa by Dr. Emin Bey. The author proposed to name it (after its discoverer) *Salpornis emini*.—Prof. Flower, F.R.S., read a note on the names of two genera of Delphinidæ, which he found it necessary to change.—A communication was read from Dr. Camerano, giving a summary of the distribution of the native Batrachians in Italy.—Mr. G. A. Boulenger gave the description of a new variety of lizard of the genus *Lacerta* from South Portugal, which he proposed to describe as *Lacerta viridis*, var. *gadovii*.—A communication was read from Mr. H. O. Forbes, containing remarks on a paper by Dr. A. B. Meyer on a collection of birds from the East-Indian Archipelago, with special reference to those described by him from the Timor-Laut group of islands.—Lieut.-Col. C. Swinhoe read a paper on some new and little-known species of butterflies of the genus *Teracolus*. The author referred to and described twenty-two species, sixteen of which were new to science, and the others very rare.—A communication was read from Mr. Francis Day, F.Z.S., on the occurrence of *Lumpenus lumpetriformis* off the east coast of Scotland.—Mr. Oldfield Thomas read a paper upon the Muridæ collected by M. Constantin Jelski, near Junin, in Central Peru, during the years 1870-73. The collection consisted of ninety-two specimens, representing twelve species, mostly belonging to the genus *Hesperomys*, the nine sub-genera of which were now arranged and re-defined. One species and two varieties were described as new under the names of *Rheithrodon pictus*, *Hesperomys laticeps* var. *nitidus*, and *H. bimaculatus* var. *lepidus*.—A communication was read from Mr. W. E. Distant describing the Rynchota collected by the late Mr. W. A. Forbes on the Lower Niger. The collection contained examples of twelve species, eleven of which belonged to the Hemiptera and one to the Homoptera. Two species appeared to be undescribed.—Prof. Mivart, F.R.S., read a paper on the development of the individual and of the species as forms of instinctive action.—This meeting closes the present Session. The next Session (1884-1885) will commence in November next.

[1] *Phil. Trans.* 1859, vol. cxlix. p. 91.
[2] *Ann. der Phys. und Chemie*, Band cxxvi. p. 539.

Geological Society, June 11.—Prof. T. G. Bonney, F.R.S., President, in the chair.—Charles Edward Bainbridge, John J. Evans, William Frederick Fremersdorff, and Henry de Morgan Snell, were elected Fellows of the Society.—The following communications were read:—The range of the Palæozoic rocks beneath Northampton, by Henry John Eunson, F.G.S.—On some Zaphrentoid corals from British Devonian beds, by A. Champernowne, M.A., F.G.S.—On the internal structure of *Micrabacia coronula*, Goldf., sp., and its classificatory position, by Prof. P. Martin Duncan, M.B. (Lond.), F.R.S., F.G.S.

Anthropological Institute, June 10.—Prof. Flower, F.R.S., president, in the chair.—A paper was read on the deme and the horde by A. W. Howitt, F.G.S., and the Rev. Lorimer Fison, M.A., in which the authors traced a close resemblance between the social structure of the Attic tribes and that of the Australian aborigines. The word horde is used to indicate a certain geographical section of an Australian community which occupies certain definite hunting-grounds. Its members are of different totems; in fact all the totems of the community may be represented in any given horde. Descent being through the mother as the general rule, the child is of its mother's totem, not of its father's, but it belongs to the horde in which it was born. So, too, the children of aliens are admitted into the exclusive organisation by virtue of a right derived from their mothers. In Attica there were also two great organisations—one based originally on locality, and another whose sole qualification was that of birth—the demotic and phratriac. Both included the free-born citizens, and therefore coincided in the aggregate, but no deme coincided with any phratria, or with any subdivision of a phratria. The naturalised alien was enrolled in one of the demes, but there could be no admission for him into a phratria; if, however, he married a free-born woman his children by her were not excluded, they were enrolled in her father's phratria, the relationship between a child and its maternal grandfather being looked upon as a very near tie of blood. Thus, making all necessary allowance for difference of culture in the two peoples, it appears that the phratriac is analogous to the social organisation in Australia, while the demotic divisions correspond to the Australian hordes.—A paper by the Rev. C. A. Gollmer, on African symbolic language, was read, in which the author described the method by which the natives of the Yoruba country send messages to one another, and communicate their wishes by a variety of tangible objects, such as shells, feathers, pepper, stones, coal, sticks, &c.

EDINBURGH

Royal Society, June 16.—Dr. Saug, Vice-President, in the chair.—The Astronomer-Royal for Scotland communicated a paper on micrometrical measures of gaseous spectra, which was accompanied by several elaborate maps of the spectra examined. The instrument used gave a dispersion of 1200 degrees. Among several curious results indicated was the fact that the spectrum of nitrogen indicates it to be a compound, while oxygen and hydrogen act as if simple substances. Prof. Smyth also gives the spectra of carbon-oxygen and carbon-hydrogen compounds.—Dr. Saug read a paper on the computation of recurring functions, by the aid of chain-fractions.—Prof. Tait communicated a note by A. H. Auglin on an extension of Euclid I. 47. Mr. Auglin showed how, by regarding equiangular and equilateral polygons described on the sides of a right-angled triangle as being composed of equal isocceles triangles the methods of Euclid's First Book might be used to prove the 47th Proposition as extended to equiangular and equilateral polygons.—W. E. Hoyle gave a paper on the Ophiuroidea of the Faroe Channel.

PARIS

Academy of Sciences, June 23.—M. Rolland, President, in the chair.—Researches on the origin and transformations of the

nitrates universally present in the vegetable kingdom, by M. Berthelot. From his experiments the author infers that the nitrates, derived partly from the soil, partly from the atmosphere, are found chiefly in the stems of plants, varying from almost infinitesimal quantities to 15 thousandths in the potato, 28 thousandths in wheat, and even 150 thousandths in certain species of Amaranthus.—Report on the documents, published by the Minister of Public Works, connected with the mission undertaken by Lieut.-Col. Flatters to the region south of Algeria, by M. Daubrée. The object of this mission, carried out in the winter of 1880–81, was to ascertain the possibility of constructing a railway across the Sahara, between the French possessions on the Mediterranean and the Atlantic. As far as the Asiu wells, the extreme point so far reached, no serious obstacle was met, and for over 350 miles to the south of Wargla, the ground was found to be so easy that a line might be constructed to this point at an outlay of about 4000*l*. per mile.—Arithmetical commentary on a formula of Gauss (continued), by M. de Jonquières.—Report of the Suez Canal International Committee, meetings of June 16 and 19, communicated by M. de Lesseps. The Committee pronounces in favour of simply widening the Canal in preference to constructing another.—Election of Dr. Salmon as Corresponding Member for the Section of Geometry in place of the late Mr. Spottiswoode.—Report on two cases of secondary suture of the central nerve attended by rapid restoration of the functions of the nerve in the paralysed parts, by M. Tillaux. — Remarks on some phenomena of chemical occlusion: occlusion of one gas by another, by M. P. Schutzenberger.—On a new method of synthesis of nitrous organic compounds; complete synthesis of xanthine and methylxanthine, by M. Arm. Gautier.—Researches on the formation and structure of the gray embryonic substance in the spinal marrow of the higher vertebrate animals, by M. W. Vignal.—Description of the Calocoris, an insect of the genus Phytocoris, which infests the vine and young grape, by M. G. Patrigeon.—Note on a generalisation of the theory of reduced quantities, by M. Em. Barbier.—Remarks on the height and annular form of the mountains on the planet Venus, by M. P. Lamey. From a careful study of a series of designs of the planet executed at Grignon during the present year, the author infers that a perfectly circular protuberance in the southern hemisphere, presumably a volcano, has an elevation of probably not less than seventy miles. He argues that this enormous height is in no way incompatible with the volcanic nature of the planet.—Description of a new mercurial electro-dynamometer, by M. G. Lippmann.—A study of the spheroidal state of fluids and their freezing-point under pressure, by M. J. Luvini.—Note on the glyoxalbisulphites of potassa and baryta, by M. de Forcrand.—Researches on ferricopotassic tartrate, ferric arseniate, arsenite of iron, and other colloidal sulphates of iron, by M. E. Grimaux.—A comparative study of the alcohols derived from the xylenic carburets, by M. A. Colson.—Remarks on the natural saltpetres of Chili and Peru, in connection with rubidium, cæsium, lithium, and boric acid; practical application to the beet-growing districts in the North of France, by M. Dieulafait.—Distribution of the saline substances of the grist in the various products of the corn-mill, by M. Balland.—Note on the poison of the Hymenoptera, and anatomical description of their secreting organs, by M. G. Carlet. The author concludes that the poison of these insects is always acid; that it is composed of two distinct liquids, one extremely acid, the other slightly alkaline; and that these two liquids are secreted by two special glands, the *acid* and the *alkaline* glands, which discharge their contents at the base of the gorgeret, or sheath of the sting.—On a new type of elastic fibre observed in the larva of Eristalis, by M. H. Viallanes.—On the development of the digestive tube of the Limaceæ, by M. S. Jourdain.—Note on the Geological Map of France, scale 1 : 500,000, prepared by MM. G. Vasseur and L. Carez. This map, the first executed since 1842, will be completed in forty-eight sheets early next year. Several of the sheets have already gone to press.

Berlin

Physiological Society, May 30.—Dr. Falk has, in the course of an investigation of the phenomena of death by drowning, determined experimentally certain relations of the cutaneous nerves to respiration for which he claims a manifold practical importance. When rabbits are suddenly plunged into cold water of about 5°–7° C. a cramp of the expiratory muscles occurs, and respiration ceases in the position of expiration. This effect of cutaneous stimulation occurs even when the superior laryngeal nerves have been cut through. The recognised relation of the trigeminus to expiration, which manifests itself in the occurrence of sneezing upon stimulation of the nasal mucous membrane, was also confirmed in these experiments; when the face only was dipped into the cold water the expiratory cramp was very violent, whereas the sudden immersion of the hinder extremities and of the lower part of the body was inoperative, the effect not being produced till the breast and the neck were stimulated. The respiratory track of the larynx was the only part of it that was affected, when the face was not immersed, but the glottis closed completely when the trigeminus was stimulated. When the cutaneous nerves were more powerfully stimulated so that pain occurred, a violent inspiration set in. The methods of restoring persons apparently dead and still-born children to life have, according to Dr. Falk, no relation to the effect of cutaneous stimulation upon respiration; the dashing of cold water upon the chest acts upon the heart alone, and the pouring of water on the nape of the neck and back of the head acts upon the medulla oblongata.—Dr. A. Baginski, who had previously discovered the occurrence of xanthine bodies in the urine of children who were affected with nephritis, has followed up the occurrence of these substances, and has determined, by comparative examination of healthy and sick children, that xanthine occurs only in nephritis; and that the quantity of it present increases proportionately with the malignity of the attack. The circumstance that methyl xanthine resembles theobromine in its chemical composition suggested an examination of the tea, in which considerable quantities of guanine, xanthine, and hypoxanthine were detected. In the pancreas when putrefying the amount of xanthine substances were diminished, and of these guanine was the one of which, proportionally, most was destroyed by putrefaction. Next came xanthine, and hypoxanthine had the greatest powers of resisting putrefaction. The presumption that hypoxanthine would not even be destroyed by digestion was not borne out. After exhibition of hypoxanthine the quantity that occurred in the urine was not above the normal but rather a little below it. Its effect upon the heart was a very remarkable one, it occasioned much more active and energetic contractions, so that hypoxanthine may be regarded as a body which has the power of increasing the cardiac activity, and perhaps it is to this that the beneficial effect of tea-drinking may be attributed. Dr. Baginski intends to follow up the investigation of these interesting substances further.

CONTENTS

THURSDAY, JULY 10, 1884

THE CHOLERA GERM

AT the present moment when the Continent has again become the battle-field between cholera and the human race, all questions concerning the cause, diffusion, and prevention of the cholera virus must take a prominent place in the deliberations on the best sanitary measures to be adopted in combating this insidious foe. Almost all practical preventive measures in this country and on the Continent as regards cholera and other infectious maladies are based on the assumption—supported by a good deal of evidence both theoretical and practical—that the virus is particulate, and, as indicated by its self-multiplication within the affected person, is a living organism. But the nature of this supposed organism of cholera has, until quite recently, been altogether mysterious. As is well known, Prof. Koch and colleagues, sent out last year by the German Government to investigate the cholera in Egypt and India, have ascertained that in the rice-water stools voided by patients suffering from the disease there are present, besides micrococci and bacilli common to the evacuations of other than cholera patients, peculiar curved bacteria, so-called "comma-shaped" bacilli, which Koch has not been able to discover in any cases of diarrhœa. These "comma-shaped" bacilli Koch has succeeded in isolating by artificial culture. Unfortunately cholera has hitherto not been found transmissible to the lower animals, and therefore the function of these "comma-shaped" bacilli must at present remain unknown. All we can therefore say is that Koch has shown that in cholera evacuations there exist, besides micrococci and straight bacilli, other organisms also characterised by this —that they are curved or comma-shaped. Whatever else has been said by Koch, his followers, and critics, scientific and daily papers, as to these "comma shaped" bacilli being the cause of cholera, is simply and purely a supposition, which, as we shall presently show, is wanting in the most essential elements.

First and foremost, Koch has been unable to find anything of this "comma-shaped" bacillus in the blood or tissues in any stage of cholera. Now all experience on cholera teaches that, whatever its cause may be, the alimentary canal is not the only passage through which the cholera-poison enters the system, but that its entrance through the respiratory organs is also an established fact. For this reason it is necessary to assume that, as in other infectious diseases, it passes in the stage of incubation of the disease through the blood and system. The symptoms of cholera, the whole nature of the disease, shows that it is not a local distemper of the alimentary canal, but that the latter is merely a symptom of the malady, as much as in typhoid fever the distemper of the ileum and spleen, or in scarlatina that of the skin, throat, and kidney. Had Koch found the "comma-shaped" bacillus in the blood or the tissues, *e.g.* the blood-vessels of the alimentary canal, mesenteric glands and spleen, the nature of this "comma-shaped" bacillus would have been as obscure as ever, but still there would have been some sure element in the chain of surmises. Of course it might be argued, and as a matter of fact it is argued by Koch in the reports to his Government, that the bacillus, having found entrance into the cavity of the intestines, there multiplies, and produces some ferment, which, absorbed into the system, sets up the whole chain of appearances constituting the symptoms of cholera. This is quite possible, and to a certain limited extent is borne out by experience, notably in the case of putrid or pyæmic poisoning, where, owing to the presence of putrefaction in a wound, the products of putrefaction—the sepsin—absorbed in sufficient quantities into the system, create the above disease, often terminating fatally. In this case no specific organisms are detected in the blood or tissues; their presence is limited to the wound only, and their effect is merely this, that some ferment—ptomaïne or some other substance—produced by them is absorbed into the system.

That this should also be the case in cholera is, as we just said, possible, but it is not probable, for the simple reason that the cholera virus in a large percentage of cases enters the system by the respiratory organs, and therefore it must be assumed in these instances to pass into the general circulation, and consequently, if it is to be identified, must be identified in the blood or tissues.

The practical consequences of an assumption that the cholera-virus passes into the system exclusively by the alimentary canal, and that it has its breeding-ground in the latter only, are so great, that before acting on such an assumption the basis for it ought to be established, which it certainly is not.

Secondly, is it a well-established fact that this "comma-shaped" bacillus is present only in cholera evacuations? If it should be found that this bacillus is absent from the alimentary canal in all other diseases, then we could at best recognise it as pathognomonic, but it by no means follows that it is also pathogenetic.

I have lately had the opportunity of inspecting this "comma-shaped" bacillus in specimens prepared by Koch, from the rice-water evacuations, and also in artificial cultures, and I have fully convinced myself of its reality. But I possess prepared specimens of evacuations of patients suffering from severe diarrhœa (in an epidemic outbreak of diarrhœa in adults in Cornwall in the autumn of 1883, and investigated by Dr. Ballard, Inspector to the Local Government Board), in which specimens, besides micrococci and straight bacilli, there are undoubtedly present bacteria which, in shape and size and mode of staining, so closely resemble the "comma-shaped" bacilli of cholera that I am unable to discover a difference between them. I have, however, not made any artificial cultivation of them, and therefore cannot say whether there exist any differences between the two, notably as regards their mode of growth.

Here is one other point to which we wish to draw attention: as Cohn (*Beiträge zur Biologie der Pflanzen*, Heft ii.) has shown, and as is now generally accepted, a rod bacterium which is characterised by being curved is regarded not as a bacillus but as a vibrio; and it is not quite clear why, unless for the sake of novelty, Koch, generally accepting Cohn's terminology, should in the case of the cholera bacterium have deviated from it, and should not rather have spoken of it as a

vibrio, because a vibrio, and particularly a *Vibrio rugula* (sp. Cohn), is the organism which he describes as a "comma-shaped" bacillus. E. K.

SULLY'S "OUTLINES OF PSYCHOLOGY"

Outlines of Psychology, with Special Reference to the Theory of Education. By James Sully, M.A. (London: Longmans, Green, and Co., 1884.)

AT the present time no one is so well qualified as Mr. Sully to write in the English language a text-book of psychology. Himself not committed to any of the systems of philosophy, he is unsurpassed in his knowledge of all, while we do not think it is too much to add that there is no one in this country who can be said to equal him in his acquaintance with the literature of pure psychology. Moreover, the weight of his information is ably balanced by that of his judgment, and therefore we were prepared to expect that in the often difficult task of drawing the lines between philosophy and psychology, he would furnish in this text-book and in this particular a brilliant example of scientific discrimination. After having carefully read his work with this consideration before our mind, we are glad to allow that our expectation has been fully realised, so that in no case can we say that we have found a philosophical theory doing duty for a psychological fact, or a psychological doctrine unduly coloured by the use of any philosophical spectacles. And this carefulness of method is the more creditable to the author, inasmuch as he nowhere avoids pointing out the relations in which this and that truth of psychology stands to this and that system of philosophy.

The work, which runs to about 700 pages, is conveniently arranged in large and small print paragraphs, with headings in large type, while copious foot-notes give references to all the more important literature on each point as it arises. "Outlines of Psychology" is thus a treatise well adapted to fulfil one of the most important functions of a text-book, viz. that of reference. But the main object which Mr. Sully has in view is that of supplying a text-book for educational purposes, and in order to further its usefulness in this respect he systematically travels beyond the "outlines of psychology" in seeking, as he says in the preface, "to give a practical turn to the exposition by bringing out the bearings of the subject on the conduct and cultivation of the mind. With this object I have ventured here and there to encroach on the territory of logic, æsthetics, and ethics, that is to say, the practical sciences which aim at the regulation of mental processes. Further, I have added special sections in a separate type dealing with the bearing of the science on education."

It will thus be seen that the work is designed to meet the wants of divers classes of readers—teachers as well as students, and professed psychologists as well as beginners. But, owing to the arrangement of the subject-matter and to the employment of different kinds of type, confusion between the several objects which the writer has in view is avoided, while each class of reader can immediately find what it is intended that he should read. For our own part we have found profit in not skipping anything; there is advantage to be gained by reviewing even the elementary truths of psychology when these are so clearly marshalled in logical order.

If we were asked to indicate in what one respect more than another the present text-book of psychology differs from its predecessors, we should say that it does so in giving prominence to the principles of development. Without expressly espousing the theory of evolution, Mr. Sully carries through his exposition a latent reference to it, and clearly shows that he considers one of the most important duties of the present-day psychologist to be that of tracing on the one hand the probable influences of heredity upon mental constitution, and on the other the historical order of events in the psychogenesis of the individual. This leads him to assign a prominent place to the literature which of late years has joined the philosopher to the sect of baby-worshippers; and it is evident, from the number of original observations which are scattered through the book, that Mr. Sully must himself have spent no small amount of time and devotion at the shrine. Here is one of his experiences, in which "a little girl of 4½ years once drove her mother to one of the most difficult problems of philosophy." On asking why a wasp could not hurt a window-pane with its sting, and on being told in answer, "Because the window-pane has no nerves and so is not able to feel," the child perplexed the learning of the household by asking—"Why do nerves feel?" We quote this little incident in order to cap it with one of a still more embarrassing kind, which we were told a short time ago. Another little girl of the same age was silently watching her father write his sermon, and after protracted observation put to him the somewhat difficult question—"Papa, does God tell you what to write in a sermon?" With some little hesitation our clerical friend replied in the affirmative, whereupon he was ignominiously nonplused by the further question—"Then, papa, why do you scratch it out again?"

Where so much work has been so well done, the function of criticism would be an ungracious one. Nor, indeed, is it an easy thing to pick, and still less to find, a hole in Mr. Sully's armour. The most important of the doctrines which we are disposed to question is the one which says, "In later life we rarely if ever judge without making a verbal statement or proposition externally or internally" (p. 392). This doctrine is no doubt one that is very generally accepted, but it appears to us, with as little doubt, absolutely untrue. Unless we limit the term Judgment to the very act of Predication (in which case the term is divested of all its distinctive meaning), it appears to us as obvious as anything can be that in order to form a judgment there is no need to frame a proposition. Thus, for instance, to adopt Mr. Sully's illustrations, whether by an immediate act of observation I judge "This rose is blighted," or conclude from certain signs in the sky that it is going to rain, in neither case is it necessary for me to clothe the judgment in words, "externally or internally" spoken. The *judgment* (as distinguished from the statement of it) is in both cases formed quite independently of speech, in the same manner as are the so-called "practical judgments" of infants and animals. But not only so. Even with respect to the more elaborated judgments which belong to what Lewes called "the logic of signs," we do not believe that, when once the needful structure of conception has been erected by the scaffolding of verbal signs, it is then always necessary to revert to this scaffolding every time that the conceptions are required for the

purposes of a judgment. The finished conceptions are known to be standing, as it were, already built, and do not require to be mentally named, or newly reconstructed, in every act of thought. And similarly with respect to propositions, although we cannot doubt, from inquiries which we have made, that some eminent thinkers habitually employ the "*verbum mentale*" in the mechanism of their thinking much more than others equally eminent, yet we do not believe that any man who ever thought was in any large measure really dependent upon this *verbum*. Indeed it appears evident that in all cases that mental seizure of perceived relations, in which an act of judgment as such consists, must be prior to the statement of the act, whether internally or externally. No doubt the statement may serve in many cases to give clearness and precision to the judgment after it has been formed; but even here we are convinced that some thinkers are much less dependent upon this artificial assistance than others. In some minds whole trains of conscious reasoning upon matters of the most abstruse kind may pass without a single act of predication being performed, until the necessity arises for considering how these trains of reasoning may be expressed to other minds.

We have dwelt upon this point, because it is one to which we should like to see the attention of our psychological readers directed. But we may now conclude by saying that every one who desires to have his information on psychological matters brought up to date ought to procure this excellent text-book. It must have involved immense labour on the part of its author, and the result is one which deserves the substantial gratitude of the public.

GEORGE J. ROMANES

OUR BOOK SHELF

Numerical Exercises in Chemistry. By T. Hands, M.A., Science Master in Carlisle Grammar School. (London: Sampson Low and Co., 1884.)

THERE are now several of these small books of questions in chemical arithmetic before the public, and although serving a very useful purpose, the tendency to run into purely arithmetical exercises with a flavour of chemical connection or application is apparent to a greater or lesser degree in all of them. This is to be regretted, as there is plenty of room for purely chemico-arithmetical problems and questions. And then again it is not desirable that more time than necessary should be taken up by the chemical student in solving arithmetical problems, seeing the immense amount of work to be done by the chemical student before he attains to a very moderate knowledge of the subject. We have an ever-increasing number of students who pass elementary and advanced examinations but who are completely fixed by problems in practical or theoretic chemistry whose solution demands only a knowledge of the fundamental properties of the elements and the effects of mass or temperature. The questions in this little book are varied and not too numerous in any one section, and should be useful as leading up to chemical *thinking*.

Chimie Elementara. Partea I. Metaloide. By Prof. Licherdopol. (Bucharest, 1884.)

THIS is a text-book in use in the technical school in Bucharest, and for an elementary work contains a very large amount of matter, and with the usual exception of having theoretical considerations in the early part of the book it is well arranged. The present part deals with the so-called non-metallic elements, which are arranged and treated in order of valency. At the end of each section are questions and problems. The appendix contains some good tables for the qualitative testing for acids and non-metallic substances and on rational formulæ, both for mineral and organic substances. The work has a decidedly practical stamp, and should be well adapted for a technical school of a general character.

Voyages of Discovery in the Arctic and Antarctic Seas and Round the World. By Deputy Inspector-General R. McCormick, R.N., F.R.C.S. Two vols. (London: Sampson Low and Co, 1884.)

IT seems rather late in the day for Dr. McCormick to tell the story of the various voyages in which he took part, in two handsome and richly illustrated volumes. He is certainly extremely diffuse, and has evidently no idea of perspective and proportion. However, we can pardon much in a venerable officer who has done good service to his country and to science in his day, especially since his volumes contain much that is really valuable. Dr. McCormick was with Sir Edward Parry in 1827 in the attempt of the latter to reach the Pole from Spitzbergen. But the greater portion of the first volume is occupied with the journal he kept when serving as surgeon in Ross's Antarctic Expedition of 1839-43; curiously he mentions only once or twice the name of Sir Joseph Hooker, whose classical Antarctic and other Floras were the result of his exertions during the same expedition. The second volume is occupied with the account of a boat voyage by Dr. McCormick in search of Sir John Franklin, and with his own exceedingly minute autobiography. The student of science will find much to interest him in these volumes; the very large-scale illustrations of the forms of ice seen during the Antarctic voyage are of special value.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Science and the Sandhurst and Woolwich Examinations

AS one of a class of private tutors who, because they possess the secret of successfully preparing lads of moderate ability for the above examinations, are invidiously or ignorantly termed "crammers," I should like to say a few words on the subject of your excellent leader in NATURE of June 26 (p. 189).

With the opinions and suggestions therein propounded, I most cordially agree, and I believe they would be indorsed by every true friend of real education throughout the country. One or two of the facts connected with the table of percentages admit of an explanation founded on considerations besides those adduced by the writer, the exposition of which will, I think, tend to confirm still more the truth of the general conclusions arrived at. Thus the high percentage of success in French, both for Sandhurst and Woolwich, depends a good deal on the fact that it is compulsory for the preliminary examination in each case, a candidate naturally pursuing for his "further" examination, a subject which he has already partially acquired. It is, besides, *notorious* that this subject is highly marked.

Again, the percentage in the geography and geology for Sandhurst would not be so high were it not that a non-classical Sandhurst candidate generally pitches upon it as offering the easiest choice in the way of a fourth subject, because six questions in the paper are pure geography, a subject which is again obligatory for his "preliminary," while the geology, as the writer remarks, may perhaps be more readily crammed than any other scientific subject.

In the case of a Woolwich candidate who relies mainly on his mathematics, the necessity of a fourth subject is not so much

felt, and, besides, his mathematical tastes would naturally incline him, of the two, to take up electricity rather than geology.

It is lamentable to think that this radical change, by which science is virtually shelved, is solely due, as the Duke of Cambridge said, to a desire on the part of the authorities to eliminate the "crammers," and get boys passed into Sandhurst and Woolwich direct from the public schools.

Now, however desirable the approximation to such an ideal may be to the authorities, or even the public schools, it is very questionable whether it will prove equally desirable for the service, unless indeed means are taken to insure that the schools will do their work more efficiently than heretofore. This is scarcely likely to be accomplished by cutting science or even English literature out of the scheme, under the pretence that such subjects admit of being "crammed." The truth is that in these points the authorities have simply pandered to the present inability of the schools to teach these subjects successfully. Nor is it likely that the schools will be any more successful in the teaching of French and German up to the new standard, than they have been up to the old. In this, as in everything else, the tutors by the new scheme are really left masters of the situation.

Why do not the authorities accept what the Marquess of Salisbury maintained was inevitable so long as competitive examinations existed, and instead of attempting the impossible task of uprooting the tutor, place him on a recognised official footing, give him in place of the prestige which efficiently insures the maintenance of discipline at the large public schools, the protecting ægis of a few simple rules which every tutor would be obliged to enforce, and the breach of which would render the offender liable to be denied entrance into the service? This would correct the evils which are prevalent at some of our larger army "coaching" establishments, and then there need be no reason for the pretence under which a candidate is supposed to be better fitted for life by a total ignorance of science and the literature of his own country, in lieu of which, like a parrot, he has been taught to chatter one or two foreign languages.

Tunbridge Wells, July 1 E. DOUGLAS ARCHIBALD

Animal Intelligence

HAVING noticed some time ago a number of letters in NATURE on the above subject, I venture to publish an instance, which came under my own observation last month, of extraordinary intelligence in a rat. I was standing in the doorway of a large shed, the further end of which had been partitioned off with bars to form a fowl-house, when I was attracted by a gnawing and scraping noise; turning round I saw a rat run from a large dog-biscuit which was lying on the floor, and pass through the bars. Being curious to watch if he would return, I kept quiet, and presently saw a well-grown specimen of the "common brown rat" (*Mus decumanus*) come cautiously forward, and after nibbling for a short time at the biscuit, drag it towa d the bars, which are only two inches apart, and would not allow the biscuit to pass. After several unsuccessful attempts he left it, and in about five minutes returned with another rat, rather smaller than himself. He then came through the bars, and, pushing his nose under the biscuit, gradually tipped it on edge, rat number two pulling vigorously from the other side; by this means they finally succeeded in getting a four-inch biscuit through a two-inch aperture. Not feeling pleased that my dog's biscuits should be used as food for rats, I threw a hammer at them and picked up the biscuit.

I think the conduct of these animals showed a wonderful amount of intelligence; it was evident that the first rat saw that to get the biscuit through the bars it was necessary that it should be on its edge, and, not being able to tip it and pull at the same time, he gained the assistance of a friend.

The short space of time during which he was absent, and the concerted ac ion, show also that they must have some wonderfully facile means of communicating ideas. T. W. KIRK

Colonial Museum, Wellington, New Zealand, May

ABOUT twenty miles from this, in the town of Larne, there resides a gentleman in the possession of a cat, which is so great a favourite that every day a plate and chair are placed for her beside her master, whose repast she shares with supreme content.

One day for some reason the dinner was postponed, but the cat came in at the usual hour. She was evidently much disconcerted at seeing nothing going on, walked once or twice disconsolately round the table, then disappeared. Shortly afterwards she returned with a mouse, which she laid on her master's plate, then going away, she came back a second time with a mouse, which she put on her own plate. She postponed further proceedings until her master returned, when she immediately began to purr and rub herself against his legs, as much as to say, "See how nicely I have provided for you."

Between this town and the village of Holywood there is a country house which happened to take fire last week. The cat of the house, which had access to the servant-maid's apartments, ran up and pawed the young woman's face. Being very drowsy, the girl turned to sleep afresh. The cat, however, after some interval returned, and proceeded to scratch the girl's face to such purpose that she rose, and, smelling the fire, wakened the other members of the household, and the flames were extinguished.

A nephew of mine who is fond of cats generally keeps three or four, and by dint of pains and kindness teaches them a variety of tricks. I saw one of them sipping cream from a teaspoon, which it held between its two forepaws. I might relate quite a number of other particulars about cats, but do not like to trespass further on your space. The foregoing, along with the other details which I have already furnished, are perhaps not unworthy to be placed beside the interesting particulars narrated by the younger Cuvier and Mr. Romanes in reference to the intelligence of animals. HENRY MACCORMAC

Belfast

Butterflies as Botanists

THE caterpillars of Mechanitis, Dircenna, Ceratinia, and Ithonia feed on different species of Solanaceæ (Solanum, Cyphomandra, Bassovia, Cestrum), tho e of the allied genus Thyridia on Brunfelsia. Now this latter genus of plants had been placed unanimously among the Scrophularineæ, till quite recently it was transferred by Bentham and Hooker to the Solanaceæ. Thus it appears that butterflies had recognised the true affinity of Brunfelsia long before botanists did so.

There is yet another and more curious instance of our butterflies confirming the arrangement of plants in Bentham and Hooker's "Genera Plantarum." Ageronia and Didonis were formerly widely separated by lepidopterists, being even considered as constituting distinct families, but now they are to be found beside one another among the Nymphalinæ, and the structure of their caterpillars leaves no doubt about their close affinity. The caterpillars of Ageronia feed on Dalechampia, those of Didonis on Tragia. Now these two Euphorbiaceous genera were widely separated by Endlicher, who placed the former among the Euphorbieæ, the latter among the Acalypheæ; Bentham and Hooker, on the contrary, place them close together in the same sub-tribe of Plukenetieæ, and thus their close affinity, which had been duly appreciated by butterflies, has finally been recogni-ed by botanists also. FRITZ MÜLLER

Blumenau, Santa Catharina, Brazil, June 1

Christian Conrad Sprengel

WILL you allow me a short reply to Prof. Hagen's letter published in NATURE (vol. xxix. p. 572)? It is evident that Prof. Hagen's statements are very far from proving what he asserted in his former letter, viz. that between 1830 and 1840 Sprengel's discoveries were known to every student in Pru sia, and I think it would be easy to any one resident in Germany to prove the contrary by simply c nfronting what the manuals of botany published at that time say about the fertilisation of flowers. Thus, as I learn from Delpino's "Ulteriori Osservazioni" (p. 88), Link ("Elem. Philos. Bot.," ii. 1837, p. 222) and Treviranus ("Physiol. der Gew.," ii. 1838, p. 343), both of whom, according to Hagen, were entirely acquainted with Sprengel's discoveries, adopt Cassini's erroneous view of the fertilisation of Campanula being effected through the collecting-hairs of the style instead of through the stigmatic papillæ; and this must have been almost impossible for any one acquainted with Sprengel's excellent account of *Campanula rotundifolia* ("Entdeckte Geheimniss," p. 109). What Prof. Kunth, in his lectures at the Berlin University, taught about the fertilisation of flowers may be seen in his "Lehrbuch der Botanik" (1847, p. 422). Almost every line contains errors splendidly and convincingly refuted by Sprengel. Thus he considers as contrivances serving

to aid the self-fertilisation of the flowers the collecting-hairs on the style of Campanulaceæ and Compositæ (see Sprengel, pp. 109 and 370), the pollen-masses of Orchideæ and Asclepiadeæ being fixed near the stigma (Sprengel, pp. 401 and 139), the movements of the stamens of Parnassia, Ruta, and Saxifraga (Sprengel, pp. 166, 236, and 242), as well as the movements of the stigmas of Nigella, Passiflora, and Epilobium (Sprengel, p. 280, 160, and 224). I do not know how to reconcile these errors with Prof. Hagen's statement that Kunth was "beyond doubt acquainted with the facts" discovered by Sprengel. He "beyond doubt" never read Sprengel's book, and I can explain those numerous and crass errors of one of the most celebrated botanists only by the assumption that at that time Sprengel had fallen into almost complete oblivion among German botanists, and remained so till, as Prof. Möbius justly remarks (NATURE, vol. xxix. p. 406), "the value of his treatise in its bearing on the theory of selection was first recognised by Charles Darwin." FRITZ MÜLLER

Blumenau, Santa Catharina, Brazil, May 25

Voracity of the Drosera

I AM not aware that the Drosera has been noticed to capture so large an insect as the dragon-fly, *Pyrrhosoma minium*. Passing a pond-side on a bright June morning, where this insect was flying plentifully, and near which *Drosera rotundifolia* was growing in abundance, I saw that many of these insects had fallen victims to the carnivorous propensities of the plant. On one spot about a foot square I counted six plants which had captured specimens of the dragon-fly, besides smaller insects. One plant had possessed itself of two of the dragon-flies, one being partially digested and the other freshly caught. The Drosera plants, being young, were in many instances less in expanse than the dragon-flies caught upon them, which measure about two inches across the wings, with a body about one inch and a half long. The dragon-flies appeared to be attracted to the plants by the reflected sunlight glistening upon the beads of fluid secreted from the leaves, and from which the plant receives its common name of "sun-dew." Those dragon-flies which I saw caught hovered over the plants about a second, at a distance of three or four feet, and then darted upon the plant, when they were instantly caught. A. BALDING

Wisbech, July 3

Lightning

AT this time of the year one commonly reads of persons being struck dead, blind, or senseless by lightning; some of the phenomena are very puzzling, especially in cases where persons are but slightly injured.

On June 6, 1881, I was in the open country near the sea between Gosport and Southampton, in a place where there was no shelter. Here I was suddenly overtaken by a violent storm of thunder, lightning, and rain. Before I had time to think of escape, the air became darkened by the pouring rain, and, to save myself from a drenching, I perhaps foolishly put up my umbrella; at the same instant I saw a blaze of fire on the right-hand side of my face; the thunder burst at the same moment, and a violent wrenching pain seized the fingers of my right hand (which held the umbrella), the pain instantly travelling to my elbow and shoulder, where it ceased. With the exception of a strong pain in the arm like rheumatism for the rest of the day, I felt no further ill effects.

There is a blind beggar sometimes seen about here who carries a label stating that his eyes were destroyed by lightning; there is no iris to either eye; both are quite white. One day lately I asked him how he lost his sight. He said that he was leaving a country public-house during a thunder-storm, and he received the blow from the lightning at the street-door, as he stood on the top of a short flight of stone steps. He could only remember seeing the blaze of the lightning, and being hurled to the ground down the steps into the street. On his senses returning, he was blind. He states that he had a little glimmering sight at the time of recovery, but first one eye and then the other soon became totally blind.

A few years ago several letters appeared in NATURE regarding the descent of balls of fire in thunder-storms. On July 5, 1881, whilst watching a storm from my windows at 11.30 p.m. I distinctly saw in the south a ball of fire drop from the clouds to the earth. The descent was rapid, but not comparable with lightning, and with an inclination to the east. The ball appeared large, and about one-half or one-third the apparent size of the moon. A carpenter who was working for me at the time, Mr. George Hebb, on calling upon me a few days after the storm, told me (I had not previously mentioned the matter to him) that he had seen the descent of the same ball of fire from Mildmay Park whilst he was walking towards the south. It is the only example I have seen. WORTHINGTON G. SMITH

Solar Halo

ON Friday, June 27, about 5 p.m. my attention was drawn to a solar halo which lasted for about two hours from that time; the circular part of the halo was white, and about the size of an ice halo, the sun apparently about four times its proper size and of badly-defined outline; all within the halo was darker than the rest of the sky, and vertically over the sun there was about an octant of another circle (?) touching the first one, but prismatically though not brilliantly coloured. On Saturday night there was a strong pink glow from 9 to 9.30 in the north-north-west, with a greener sky near the moon, which was itself also somewhat green. W. W. TAYLOR

INSECT PESTS IN THE UNITED STATES[1]

THIS volume is issued under the auspices of the Department of Agriculture, and relates entirely to five insect pests. The book is full of matter of general as well as of purely scientific interest, and abounds in suggestions for checking and exterminating the pests of which it treats.

One rises from its perusal with a sense of thankfulness for our temperate climate, insularity, and moderate dimensions. These conditions are unfavourable to excessive multiplication of insect life; and hence we escape the locust, the canker-worm, and the palmer-worm, in their full devastating energy. The connection between solar activity and swarms of insects forms a special section; and the relation between sunspots and locust flights is drawn out in tabular form, showing a striking coincidence between special locust visitations and the minimum of sunspots. This is of course merely a scientific way of showing that hot summers breed insects. The Report deals with the Rocky Mountain Locust, the Western Cricket, the Army-Worm, Canker-Worm, and Hessian Fly, and the treatment of the subject is a full justification of the existence of such a Commission.

An Entomological Section of an Agricultural Department appears to be an absolute necessity in those vast regions, and the facts and phenomena are so startling as to be worthy of constant watchfulness, and this can only be secured by a special and permanent Commission. On the other hand, the powerlessness of man in dealing with the actual invading forces of the winged or creeping armies of Hexapoda is constantly exemplified. It is truly observed that the only effective method of dealing with insects is to study their habits, their structure, their weaknesses, their devolution. It is here that the entomologist shakes hands with the agriculturist. The cultivator is paralysed by the magnitude of the devastation, and the best he can do is to take such self-evident means as are at once available, such as burning, rolling, roping, or the like. The entomologist works less precipitately, but more surely, in studying the sexual and maternal habits of the *imago*, the conditions favourable to incubation, the hatching and development of the *larva*, the transformations to the *pupal* and perfect forms, and lastly, the food and habits of the mature insect.

All these and other matters are searched into by the State entomologist much upon the same principle as a Government section collects information as to the habits and resources of some nation with which it may at some time find itself at war. Thus the Entomological Commission

[1] "Third Report of the United States Entomological Commission. (Washington Government Printing Office, 1883.)

of the United States collects information which may serve a purpose in a war of extermination against the objects of its studies. The volume contains a vast amount of practical information, an extensive series of microscopic sections, chiefly relating to the embryology of insects, zoographical maps of North America, and appendixes bearing upon the subject-matter of the volume. Each destructive insect is very fully treated of with regard to its biological relations, its distribution, ravages, and methods of prevention, all of which are of great interest. A middle section of the volume is occupied with matter which may be described as pure embryology, and deals with the deepest questions which await the microscopist or the biologist. Thus the formation of the blastoderm, endoderm, mesoderm, and inner germinal cells, the phenomena of invagination, the evolution of the brain and ganglionic chain, the philosophy of metamorphosis, and the origin of wings. These matters appear scarcely germane to an Agricultural Department, and it is by no means easy to see how the discussion of such problems can throw the least little ray of light upon economic entomology. Viewed as a pursuit after pure knowledge, and a deep diving after the great mystery of life, these chapters may be considered as a contribution to our speculative knowledge. As a part of an agricultural report they are as relevant as would be a disquisition upon a fourth dimension or molecular movements in solids. At p. 295 is a Genealogy of Insects (Hexapoda), tracing from the Thysanura, followed by a detailed but highly speculative theory of the origin of the Coleoptera and other insect types. "The primitive form of beetle was probably a Staphylinus-like form, with a long narrow body, and rudimentary elytra, and carnivorous in habit." Such speculations probably are useful to their originator chiefly. We do not in fact deny their biological interest, but they are misleading in such a report as that before us. It is no doubt difficult to draw the line between what is useful and what is not, but in loading an economic report with such matter a door is opened which could scarcely be shut against any biological problem whatever. And yet some sop must be thrown to the scientific inquirer enlisted in the service of a Commission. He perchance would mope and pine if too rigidly confined to the economic side without being allowed to express his views upon deeper and wider problems. There is abundance of matter congenial to the agriculturist in these pages. It would not be just in the limits of one short article to attempt to review all the subjects of interest brought within the covers of this volume. We select as an example of the work done by the Commission that familiar enemy of our race, the locust; and we trust room will be found in these columns for a second notice of this work. "If you avoid the destruction of locusts, you will have to forget the welfare of the people: which do you think ought to be thought of first? Was not therefore Tao-choon wise and good when he said 'in killing insects one saves men?" Good Tao-choon flourished in the reign of Taï-Tzoon (dynasty Tan, from 627 ante till 649 post Christum), and he is still quoted in the Far West as an authority on locust destruction. So far back in point of time and so wide in point of distance do the Commission ransack for information, bringing all to bear upon this war. The Emperor Shen-Tzoon's orders would not perhaps commend themselves entirely to the independent voters of the free States. Thus, "whenever locusts leave desert places to go to populated ones, the local chiefs are obliged to hire poor people and have the eggs destroyed. If all of them should not be destroyed, and the locust therefrom reappear the next year, those commanders will be punished with 100 bamboo-rod blows." Again, "Once the locust appears there is no writing to be done for excuses of absence of chiefs, &c.—paper won't help—the commander-in-chief must be present." Evidently high position in the reign of Shen-Tzoon had its duties and responsibilities as well as its privileges. The practical and relentless measures recommended are thus described in the same document. "For the purpose of burning the locusts one digs a ditch 5 feet deep and 5 feet wide and twice as long. One empties the bags into the fire. As soon as the locust is in, it won't jump out. That's what the poetry means by 'delivering them over to the flames.' Even in old times they knew that if you bury a locust he will creep out again. Therefore the destruction of locusts by fire, as they did in ancient times, is the best."

The Rocky Mountain locust (*Caloptenus spretus*) is one out of about 200 species of this prolific family represented in North America. If we run our eyes over the map of North America and set aside all that portion contained between meridians 103° and 117° W. of Greenwich, and from the parallels of latitude 40° to 53°, we have the "permanent home" of this insect well before us. It is all considerably elevated, treeless, and arid, thus agreeing to some extent with the locust areas of Eastern Europe, Northern Africa, Asia, Australia, and Central and South America. It includes the greater part of Kansas, Nebraska, Colorado, Wyoming, Utah, Dakota, Montana, Oregon, Nevada, and extends far southward into Mexico. It is bounded on the north by the tree-bearing regions of British America, on the east by the great wheat-bearing regions of the Eastern States, and on the west by the higher ranges of the Rocky Mountains. This gigantic area comprises 300,000 square miles, and the annual rainfall is under twenty inches. It is all elevated, dry, and bracing, and is known physically as the arid region. It is not a wheat-growing area. Here the locust finds a permanent home, free from diseases, and suitable for breeding, and it is from these regions that, about once in eleven years, or at the minimum period of sun-spots, excursions are made and devastation is wrought. Still, while the whole of the permanent region is favourable to the locust, there are in reality but few portions of it that are adapted to its greatest increase. The largest and by far the most important of these specially favourable areas is that of Central Montana and portions of the British Possessions immediately to the north. The next in importance is that of which the Snake River Valley is the centre, while a third locality is that of Southern Utah and parts of adjoining States. We must not pause to consider the prodigious and terrible armies with their devastating effects, "darkening the sun," and "piled up in 'windrows' for miles in length." Such narrations are highly entertaining, but may be "taken as read" by most of the readers of NATURE. With reference to the treatment of this evil, it is hoped that cultivation will restrict the breeding area gradually but surely, and that the changes of climate which follow the husbandman and timber planter may also act advantageously. The active methods consist in digging trenches, sweeping the locusts into them, and burning them. This is best done when the creatures are in a torpid condition at or before sunrise. Harrowing the ground and processes of cultivation are useful in destroying eggs and larvæ. The noise of musketry and artillery prevents swarms from alighting, and is frequently employed for this purpose, as are also fires with damp weeds thrown upon them so as to cause dense clouds of smoke. Marching locusts may be arrested by strips of tin resting against posts or nailed to walls, as they cannot climb over such smooth surfaces. Other methods are referred to as having been published in previous reports of the Commission, but on the whole the means proposed and adopted are of that simple sort which would be suggested rather by common sense than by any profound knowledge of the creatures' habits.

In this respect the Commissioners have been more fortunate in their study of some of the other insect pests. One correspondent writes with regard to locusts:—"They marched uninterruptedly through the village of Co[illegible]erg (Cape Colony), over walls and houses, and

destroyed every green thing. The plague lasted for weeks, and until the insects obtained wings, when the winds soon after wafted them away to devastate the lower country, and the ocean received them. Any opposition seemed so hopeless that none was attempted."

Among the most terrible of the insect scourges which affect the vast territories of the Western World, is the army-worm. The name arouses old associations, and one involuntarily recalls "the canker-worm, and the caterpillar, and the palmer-worm, my great army which I send among you." The army-worm well deserves his name, although like most familiar vernacular appellations it may have been wrongly employed. The cotton-worm (*Aletia xylina*), for example, has been so designated; but the true army-worm is *Leucania unipuncta*, known in the earlier chronicle as the "black worm," and is the larva of a Noctuid moth, named as above by Haworth. It is difficult to give an idea of the fearful character of this plague when in obedience to solar influence it begins its march. "Almost with a shudder (p. 145) one remembers that terrible invasion of Monmouth, when the potato fields were ruined as if by fire, and the waggon wheels reeked with green dripping gore as they entered our villages. . . . That beautiful lawn of Hollywood at Long Branch was invaded by them. The emerald sward was swept as if burnt. When any of the worms came against a tree they went up it, passed over the crotch, then descended at the other side. There is no 'turn back' to this singular worm, and when their path is intercepted by a stream, on they come, until, crowded forward, a compacted mass is urged into the water to serve as a living pontoon, over which the army passes to take possession of pastures new."

Another account states that the army-worm when travelling will scarcely turn aside for anything but water, and even shallow water-courses will not always change its progress. They avoid the rays of the sun, hence during the day they crawl under stones and sticks as closely as they can crowd themselves together, like the cut-worm. They come out towards sunset and continue their mighty march. If they come to a field of grass or young grain they devour the whole of it, down to the very roots; but if it is grown up to stalks they eat the leaves only, and then usually crawl to the top of the stalk and cut off the head and drop it to the ground.

They all keep together like an army of soldiers, and usually advance in a straight line, not swerving from their course to avoid hills, hollows, buildings, or any other obstacle. On coming to a brook, they crowd into it; millions of them are drowned, their dead bodies clogging and damming up the stream in places below, producing by their decay a stench in the atmosphere of the whole vicinity most noisome and intolerable.

Monmouth County was invaded in 1880, and the following graphic sentences from the *New York Sun* will help us to obtain an idea of this calamity:—

"Trenches were seen extending for miles along the roads close to the edges of the fields, but the crops for the most part were withered and lifeless, and it was evident that the precautions had been taken too late. Very often a trench ran across a wheat-field, showing where the farmer had abandoned one portion of his crops and tried to save the remainder. Occasionally a field was seen intersected by numerous trenches, indicating that the proprietor had fought manfully against his persecutors, and disputed the ground with them foot by foot. In many places the road was literally covered with the worms, all in motion, and all moving towards the fields on either side. Thousands and tens of thousands were crushed beneath the waggon wheels and under the horses' feet, but the rest passed on. And at intervals spots were passed where an imaginary line seemed to be drawn across the road beyond which the army-worms could not pass. For a certain space beyond, sometimes for a distance of two or three miles, not only the roads, but the adjoining country was free from the pest. Not a worm was to be seen until, the clear space passed, the waggon was again rolling over millions of them." The remedies suggested partake of the general character of the means proposed by entomologists, and are probably mostly learnt by the entomologists from the farmers and peasants. They consist in rolling, fencing, ditching, burning, coal-tarring, poisoning, "drawing the rope," which is done by two men drawing the rope in a direction at right angles to its own length.

Another pest of different habits and less widespread destructiveness is the Canker-worm (*Anisopteryx pometaria* and *æscularia*), an insect which feeds on the leaves of apple-trees, and completely ruins orchards. Entomological science has conferred a boon by suggesting methods of getting rid of this creature by taking advantage of its peculiarities. The female, like our glow-worm, is wingless, and therefore cannot rapidly spread beyond the locality where it exists. She hibernates in the earth near the roots of trees, and on the first return of spring she ascends the trunk, depositing her eggs between the leaflets of the expanding buds, sometimes even close to the ground, but oftenest under loose scales of bark. It is this peculiarity of the female which enables the fruit-grower to grapple with the difficulty. One of the best means is what is known as "hanging the band." This contrivance consists essentially of a band or ring of tin a few inches outside the trunk of the tree, and held there by a circle of muslin attached to the tin at its edge, and drawn with a cord at the top, so as to fit the tree closely and prevent the insects from going over the tin, which is coated with a mixture of castor-oil and kerosene: as soon as they touch this they drop to the ground. Troughs of oil arranged closely around the tree, or the complete isolation of the tree by fitted boarding lined on the outside by smooth tin and also fitted with shallow troughs for oil are also used. Another ingenious plan is to use a cylinder of sheet tin upon a band of line or cord. The cord forms a firm boss around the tree, and the hollow cylinder surrounds it and extends them at four inches above and below it. The female finds this an effective barrier, and it is said if she even succeeds in passing upwards to the top of the cylinder she will never *descend* in the inside so as to again reach the tree.

A good deal of interesting evidence is adduced upon the effects of "jarring and burning," or the jarring of the affected trees, after spreading a light coating of dry straw on the ground below, which is then fired without injury to the trees. A table-spoonful of Paris-green in twelve quarts of water applied to the tree with a large syringe, when, as nearly as can be judged, the worms are all hatched, is a second method. "Fall-ploughing" is a third plan, which appears to have been very successful; and, lastly, attention has been very properly drawn to the balance of power in nature by encouraging birds and parasitic insects that live upon the canker-worm. A valuable distinction has also been pointed out by the Commission between the "fall" canker-worm, and the spring species, from which it differs in many important respects, as may be gathered from its name. There are many other interesting chapters in the volume which we should have liked to at least have mentioned, but it is not our object to do more than give a good general idea as to the work of the Commission and the manner in which it is prosecuted. We therefore leave the consideration of the Hessian fly and the Rocky Mountain cricket, with a hearty recommendation to those who are interested in economic entomology to obtain this Report. J. W.

THE FORESTRY EXHIBITION

IN last week's NATURE (p. 222) we briefly noticed the remarks of the Marquess of Lothian in declaring the International Forestry Exhibition at Edinburgh open. For

several reasons it has not been in the power of some foreign Governments to be represented at the Exhibition. And in more than one case, notably that of Chili, an unforeseen accident occurred to prevent others who intended to be present. Where direct participation, in so far as exhibits are concerned, has been impossible, official maps and publications bearing on the forest service or literature of the country have been forwarded, or a representative has been commissioned officially to attend, or the efforts of private individuals have been exerted to supply the omission. The Exhibition has thus been inaugurated by the co-operation of many of the foreign and colonial Governments, and by the good wishes of all.

In the arrangement of the articles exhibited the geographical principle has been adopted, the goods of each country being together.

A scientific arrangement was very desirable, and the "classification" issued by the Executive Committee was prepared with that intention, but it was found impossible to arrange the Catalogue in accordance with it, from the imperfect details given in many of the schedules of exhibitors, and the tardy arrival of the consignments. Great latitude has been allowed to the admission of goods, which have been largely received during the week since the opening, and we believe that the very large and interesting collection from Japan will be in its place in a few days.

The Catalogue contains much valuable information, especially the portion relating to India and the Scottish Arboricultural Society, which together cover eighty pages; but it is not yet complete with respect to several colonies and foreign Governments, notably Japan. A new edition is promised, more easy of reference, where the theoretical classification of the articles on paper will agree with the actual distribution in the building.

The ground on which the buildings are erected is 5 acres in extent. The main building is 650 feet long by 55 feet broad, with three annexes, each 150 feet long by 55 feet broad, with a high central dome in each annexe.

The design of the buildings is similar to the main galleries in the Health Exhibition, Kensington. Additional annexes, 500 feet long and 25 feet broad, similar in design to the main buildings, were erected at a later stage in consequence of the large demands for space by the Japanese Government, &c.; the exhibiting area thus became one-third larger than its original extent. It is a handsome light building which produces a very agreeable effect on entrance.

The Electric Railway runs along two sides of the building, and is about 650 yards in length. On the west side of Donaldson's Hospital grounds a field 7 acres in extent was inclosed for the purpose of exhibiting woodworking machinery in motion, nurserymen's exhibits, greenhouses, iron houses, wire fencing, gates, &c. Here will be found various huts and châlets, including one from Balmoral; also the Manitoba Settler's Farm, and many varieties of models of gates, fencing materials, &c., exhibited by the Commissioner of Her Majesty's Woods and Forests, all having a connection with the wide subject of forestry.

The Indian collection occupies the south central transept, and several bays on each side; it is very large and interesting; the catalogue has a historical preface by Sir George Birdwood. The arrangement is admirable, Col Michael and his assistant having had experience in the Paris, Vienna, and Amsterdam Exhibitions.

The Index Collection of Timbers sent by the Government of India, comprises 800 specimens, with their commercial uses and habitats, and illustrates arboreal vegetation from Thibet to Cape Comorin; each specimen is carefully labelled.

In the Indian Court may be specially noticed the very valuable series of maps and diagrams executed by the Forest Survey Department under Major Bailey, R.E., who has himself arranged them in an instructive manner. The excellence of these topographical surveys can scarcely be overrated in connection with the demarcation and management of the reserved forests divided into blocks or compartments, and in the case of boundary disputes their value is undeniable. For students of forestry this is a most important feature of the Exhibition, and shows the silent progress of the great work which has been carried on by Dr. Brandon and his assistants during the past twenty-five years.

The only other country which exhibits maps showing in detail the general distribution of forests is Denmark. There are three sheets displaying the occurrence of the forests of conifers and of broad-leaved trees, also the extent of newly-planted areas and the geological formations on which they grow. There are also maps of the forest district of Kronborg which resemble those made in Germany, and are very neatly executed.

It would have been very desirable that sets of these illustrative maps had been furnished as far as possible by various Governments to assist in determining the rates of growth of indigenous trees in different countries. For instance these diagrams give the mean height from 20 to 120 years, and show that in Germany the height of beech and spruce is greater than in Denmark; but the average diameter of the latter exceeds that of the former.

In the Indian collection an interesting contribution from Col. Yule has found a temporary resting place. Marco Polo, who tells us of the existence of the roc, a bird of wonderful dimensions, further tells how the feather or quill of the roc was brought back by envoys to Madagascar or East Africa, and presented to the Great Khan. Col. Yule and Sir John Kirk seem now to have brought to light the true roc's quill in the frond of the leaf of the *Raphia* palm, which is largely used on the coast near Zanzibar for making stages, ladders, rafters, and doors. The hard ligneous frond, stripped of its leaflets, somewhat resembles a stripped feather; the largest is twenty-five feet four inches long, and twelve inches in girth at the base.

TECHNICAL SCHOOL EDUCATION AT THE HEALTH EXHIBITION[1]

IN last week's issue some account was given of the appliances, methods, and results of primary school education to be seen at the Health Exhibition, and we ventured to express the hope that this remarkable and probably unprecedented collection would be carefully inspected by as many as possible of our schoolmasters and mistresses, as well as by school managers and others. In the present article it is proposed to deal similarly with technical handicrafts and science teaching as practised not merely in England, but in those foreign countries and organisations which, as previously stated, have brought together such excellent collective exhibits.

The increased attention now being devoted to the whole subject of infant training, and the enlarged sympathy and interest with which the best modern teachers are studying the methods of Fröbel (some of the developments of which are at the basis of all so-called technical training), have justified the appropriation of a considerable space to illustrations of the Kindergarten system. The British and Foreign School Society have devoted the whole of the room at their disposal to this purpose, in order to make the display as complete as possible, and here will be found a practical answer to those who allege that "Kindergarten work is all play," for the manner in which it leads up to various trades is distinctly shown. In the Belgian Court there is also a very complete and effective Kindergarten exhibit, though it contains nothing specially new, and the

[1] Continued from p. 220

same remark applies to that of the city of Antwerp. In the gallery of the Albert Hall (No. 1374) is an admirable exhibit, in which all Fröbel's occupations are grouped round a given object in nature, illustrating the Pestalozzian system of Kindergarten teaching, as carried out in Berlin.

The subject of domestic economy, and other forms of technical and industrial occupation for girls, is illustrated in a very thorough manner by the Minister of Public Instruction in Belgium, and to a less extent by the corresponding official in France. A notice appended to the Belgian Illustrative Museum states that mere oral lessons have been found to produce no good results, and hence that this subject is taught in a "decided, intuitive, and demonstrative" manner, which has necessitated the formation of illustrative collections in each school. These will be found to be most complete, every stage in the manufacture of clothing and food, from the raw material to the finished product, being illustrated, as well as the more important points in house sanitation. No similar exhibit is to be found in the English section. The embroidery and other work of the "École professionelle de jeunes filles" will repay careful inspection. With regard to needlework generally, we are informed that some lady experts in this matter have a very high opinion of what is shown in the Belgian and French Courts, as well as of that sent by the Birmingham School Board, which appears to be the best English needlework. In this connection also a word may be said in support of the efforts now being made by the Scientific Dress-cutting Association, who show interesting demonstrations of their methods.

Turning now to the more general question of scientific and technical instruction as illustrated at the Health Exhibition, it will be remembered that one of the results of a comparison of English and foreign primary school methods was stated to be, that elementary scientific instruction formed a much more prominent feature in French and Belgian primary schools than in English. We notice with great pleasure that, in opening a higher-grade school at Manchester on Monday last, Mr. Mundella pointed out that one objection to English education was its too exclusively literary character. The practice of the Liverpool and Birmingham School Boards, and to a less extent of the London School Board (which in its exhibit endeavours to illustrate its whole system, and not merely certain features of it, as is done by the Birmingham authorities), is however a pleasing exception to this general statement. It cannot be denied, however, that a very much better foundation is laid in primary schools abroad than at home for that technical education the importance of which is now becoming so generally recognised, as evidenced by the extraordinary demand for copies of the recently published Report of the Royal Commission on the subject, and by the noble building in which the chief educational exhibits are temporarily housed.

It may be convenient, as in the former case, to notice first the foreign appliances for, and results of, technical education, the collection of which in point of interest and size is not so large, when compared with the corresponding English exhibits, as is the case with the primary schools. In the Belgian Court the collections of the Ministry of Public Instruction and of the Carlsbourg School are specially noticeable; the technological collections to illustrate the various industries are most complete, and are arranged under such heads as vegetable fibre, minerals, the animal kingdom, &c., while under the head of botany is an admirable series of specimens illustrative not merely of agriculture but of arboriculture, the various methods of grafting, for example, being clearly shown. There is also an interesting collective exhibit "des écoles industrielles et professionelles," and there are no less than three societies whose sole object is the technical and professional training of women in various trades, such as artificial flower-making, dress-making, embroidery, &c. This appears to be a new departure, which might be advantageously followed in our own country.

In reviewing the recent progress of educational legislation in France, we find that in March 1882 laws were passed which rendered obligatory (1) the teaching of the elementary physical sciences in primary schools, and (2) the performance therein of a certain amount of manual work. Accordingly, under the first of these heads we find exhibited by the Minister of Public Instruction the authorised collections of objects and apparatus used in this teaching, as well as models of simple and cheap instruments such as could be fabricated by the pupils themselves. The second law alluded to has called into existence the "École normale de travail manuel," a school probably unique of its kind, whose whole course of instruction is well illustrated by a series of photographs and specimens, and by a detailed programme. It comprises the systematic teaching of carpentry, the use of the lathe, the chemical and physical laboratory, the smith's forge, and the "fitting" shop. The whole instruction is gratuitous, and admission is obtained after a competitive examination in the lower grade schools. Fuller details about this school, as well as about the present system of education in France as a whole, will be found in the ten pages of the special educational catalogue devoted to an introduction to the French exhibits. Closely associated with this is a capital collection of work from the École des Arts et Métiers of Aix (Bouches-du-Rhone), which, together with the results of various apprenticeship and art schools, is exhibited by the Ministry of Commerce, Paris. The handicraft work of the primary schools of Vierzon and of Voiron (Isère), as well as of the technical schools at Evreux and Nantes, deserves careful examination, while in the department of agricultural industry, the work of a school at Lille is much to be commended and worthy of imitation. Among the private exhibits in the French section the most noticeable features are:—the admirable collection of objects of natural history and of science diagrams, all for school use, shown by M. Émile Deyrolle, and the wonderful collection of botanical and physiological models shown by Mme. Veuve Auzoux and M. Montaudon. Part of this is a series of anatomical models (probably the best of their kind) composed of solid pieces, which can be easily adjusted or separated, and removed piece by piece as in actual dissection. Somewhat similar models are shown by Mme. Lemercier. It is greatly to be regretted that the very high price of these excellent models is an effectual bar to anything beyond a very limited use of them.

The collection of educational appliances as used in Norway, and shown by Mr. Mallings in the gallery of the Albert Hall, deserves warm commendation. It is characterised by the same importance as attached to objective and practical teaching (as distinguished from book-information) which we noticed in the French and Belgian schools. This publishing house is one of the sights of Christiania.

Prominent among the illustrations of technical education in England, the preparations for which, as we have before stated, have not yet reached down to our primary schools to any appreciable extent, are the three rooms devoted to illustrations of the work at the Finsbury Technical School. These are specially remarkable as showing the admirable methods which characterise the whole of the work there, and which, we venture to think, deserve careful study. A room is devoted to the mechanical laboratory and appliances, and a large amount of space to the department of electrical engineering, while a special feature in the display is the printed explanatory paper of notes attached to each piece of apparatus. Another good example of English technical education is the collection of drawings and models relating to coach and carriage building, to which three organisations contribute, illustrating the alterations that occur in the conditions of locomotion. There is a very good collec-

tion of excellent specimens of school work done in the Allan Glen's Institution of Glasgow, in which the object of a two years' technical course is to prepare boys to learn trades whose mastery implies a considerable amount of scientific knowledge. University College, Nottingham, exhibits some work done in the recently established technical school attached to it, and the Engineering Department of University College, London, illustrates its work mainly by photographs and plans. The nearest approach to the handicraft school teaching as practised on the Continent, is to be found in the admirable technical work of the Central Higher School of the Sheffield School Board, in which an attempt is made to provide the proper connection between the theoretical instruction in the class-room and the practical instruction in the workshop. The Manchester Technical School, the Oldham School of Science and Art, the Clerkenwell Technical Drawing School, and the School of Art Wood carving all show praiseworthy results of technical training. Attention may here be called too to the admirable specimens of work done in the four trades-departments of the National Industrial Home for Crippled Boys; the pupils vary in age from twelve to eighteen, and having chosen a trade on entering the school, follow it for three years.

Among the results of the work of individual exhibitors, the exhibit of Mr. Robins calls for special notice, consisting as it does of a series of drawings illustrative of the general arrangements and fittings required for applied science educational buildings; these are so placed that comparisons are readily made between the arrangements adopted in various noted colleges, &c. Mr. Millis shows some excellent results of instruction in trades classes, specially models in wood and metal-plate work. Mr. James Rigg exhibits more than a hundred mechanical models specially arranged for instruction in four or five of the subjects in which the Science and Art Department examines pupils, and a smaller collection of the same kind is shown by Messrs. Gilkes and Co. Lathes of different patterns, and other mechanical tools and apparatus, are exhibited by Messrs. Holtzapffel and Co., Messrs. Melhuish and Sons, Mr. Syer, Mr. Evans, and others.

In neither of these articles has any reference been made to the appliances for elementary art instruction, nor to the special methods and apparatus used in educating the blind, and the deaf and dumb, all of which, however, are very fully illustrated. The seven classes of exhibits which come under "Group IV.—The School" (to quote the official phraseology) are also unnoticed. These comprise such important subjects as everything relating to the structural arrangements of school buildings, school kitchens, sanatoria, and infirmaries, and lastly, though by no means least in importance, the gymnastic and other apparatus for physical training in schools. Enough however has, we hope, been said to give some idea of the vast scope of this exhibition of educational appliances, and to justify the assertion made at the beginning of the first article, that probably no such extensive and valuable a collection of school appliances, methods, and results has ever been brought together before. Such an opportunity for study is not likely to occur again for some years, and we conclude by reiterating an earnest hope that it will not be lost by those most vitally interested in it.

WM. LANT CARPENTER

CHEMICAL RESEARCH IN ENGLAND

THE address of Dr. Perkin, F.R.S., to the Chemical Society at its anniversary meeting contains some sadly true statements respecting the state or rather the absolute want of state of research in chemical science in this country. After drawing attention to some interesting points in the work done during the past year, Dr. Perkin goes on in the first place to refer to the very small number of original papers contributed to the Society during the past year (a point to which attention was called in these columns a few months ago), and then compares foreign sources of research work and the probable causes of this disparity. But this portion of the address will speak better for itself than in a mere abstract, and the facts therein stated demand the most serious attention of the authorities at our seats of learning.

Last year, Dr. Perkin went on to say, my predecessor, in his address, referred to the increasing number of chemical laboratories in the United Kingdom and the greater facilities which are now afforded for the prosecution of research. After considering the number of papers which have been read before this Society during the past few years, it appeared to me that it might be useful to make some remarks as to the influence these greater facilities have had on the development of chemical science.

The first thing that attracts attention is the startling and anomalous fact that the number of papers read before the Society (and I think this may be taken as a good criterion, especially as but few have been brought before the Royal Society) is declining year by year. The largest number we ever had was in the session 1880–81, when there were 113 communications brought before us; but in 1881–82 they declined to 87, in 1882–83 to 70, and this last session to the lamentably low number of 67, or about the number we had nine years ago. And this, not only with increased laboratory accommodation, but also with the assistance offered to investigators by our Research Fund and the Government Grant. This state of things causes us to look around and see where research *is* and where it *is not* being carried on in the United Kingdom.

If we look to the laboratories of our Universities, from many of these we never hear of a research emanating, and from the rest, taken as a whole, we get but driblets at intervals. How different from the German Universities, from which there is such an incessant flow of work!

If we turn to the other laboratories connected with our colleges, hospitals, &c., with how few exceptions do we find any appreciable amount of work being carried on for the extension of the boundaries of our science; in fact, speaking in a general way, the work of our laboratories consists mainly in the students carrying out the ordinary course of qualitative and quantitative analysis, and attending one or two courses of lectures.

It is scarcely necessary to say that this is not sufficient, however well taught, to make a student a chemist; it is but a preliminary part of the training, which, being carried on as it usually is, by tables, and carefully laid down directions, gives but little scope for independent thought and action. The subsequent prosecution of scientific research, under proper supervision, however, is quite another thing, and calls out all the faculties of the student, requiring, as it does, independent thought and independent methods of working, and, moreover, gives him an insight and vivid interest in his science that nothing else will do. The preparation of chemical products, before the commencement of research, is no doubt also a very useful training if sufficiently diversified; but research is the most important of all.

The degree of Doctor of Philosophy has undoubtedly done a good deal to further chemistry in Germany, necessitating, as it does, the prosecution of original work, and now that degrees are so much thought of in this country (though why a chemist with one of our ordinary University degrees should be preferred to one who has fully given his mind to his science, and therefore has not got such a degree, it is difficult to understand), it is believed that if something analogous to the Ph.D. could be inaugurated in this country, it would help to further chemical science here also. A step in this direction has been taken at the Owens College, Manchester, but hitherto the degree has not found favour with students. It is not surprising, however, while there are so many different degrees not requiring original work as a *sine quâ non*, that such a degree should not be sought after. This difficulty, however, might be overcome by modifying the requirements for the present degrees, and requiring that original research should be substituted for book knowledge. At the London University original work is recognised, but not required.

The past neglect of research will, it is to be feared, have a more lasting influence on the progress of chemistry in this country than may appear at first sight, and in this way. Those who have been students in laboratories where the importance of

this kind of work is not recognised, advance in their positions, becoming assistant demonstrators, &c, and eventually professors, and as they have not learnt to practically realise the value of research by being in the habit of conducting it themselves, or of seeing others do so, when they become professors they will naturally not encourage students to undertake it in their laboratories, and it is to be feared that we are already suffering in this way, and that this is one of the causes why the new laboratories which have been opened are doing so little to add to our store of fresh knowledge.

It is said that students cannot be induced to stay longer than is necessary to go through the ordinary course of qualitative and quantitative analysis, and can this be wondered at when they do not see anything else going on of sufficient interest to make them feel it would be a great advantage for them to do so? Would it be the case if higher work were being enthusiastically carried on? The fact that many of our students are found to leave this country and go to Germany, where research is carried on with so much zeal, I think gives an answer to this question.

In all chemical laboratories there are without doubt different classes of students: some who have no right to be there, having no care for science; those who have not sufficient capacity to proceed with its study beyond an elementary stage; and those who are capable of becoming efficient chemists. Of course it would be but waste of time to attempt to make the first two classes remain and engage in research. It is to be feared, however, that some are not unfrequently thought to belong to the second class who really, if sufficiently interested in their science by the example of others, would be found to be possessed of no mean ability. When a young man is made to realise that he may be the discoverer of new facts, or does discover new facts, he gets a new impulse, which alters the whole current of his thoughts and actions.

There can be no doubt that when a professor, his assistants, and advanced pupils are enthusiastically engaged with research, their influence is found to act even on beginners, who, if they possess any scientific spirit at all, will realise that the ordinary course of analysis is but a preliminary thing, and will thus be induced to use their best energies to master it that they also may try their hand at original work.

That this condition of things is calculated to fill laboratories with students is seen from the fact that on the Continent, where the greatest scientific activity prevails, the laboratories are the most crowded, and this is the kind of activity we want in this country, where our students pre-eminently possess all the faculties for original work, but as they are not cultivated these are not developed.

There is also another class of students who study chemistry, but the fruit of their study is so extremely small, that it is difficult to realise that it possesses any practical value. I refer to medical students; yet there are good teachers and good laboratories employed in the work, in fact a very large amount of valuable power is used for it; but it seems almost like the employment of a large amount of power to raise a weight to a certain distance and then let it fall again, and year after year to continue the same thing, never raising it sufficiently high that it may be placed in a useful position. The present condition of things cannot but be disheartening both to students and to teachers. Medical students have so much to learn that it it is sad they should have to waste their time in studying chemistry in the way they do. If there is any value in chemical products as curative agents, if there is any value in physiological chemistry, or any importance in toxicology, surely medical students should have a sound knowledge of chemical science, and not simply learn to detect an acid and a base in a mixture, an operation which is of no value except as an intermediate exercise, to be followed by more advanced work.

The only cure for the evil appears to be either that their term of study should be lengthened, or that other subjects which are of less importance should be withdrawn from the curriculum, so as to enable them to work at this science sufficiently. Unfortunately medical men have as a rule acquired so imperfect a knowledge of chemistry themselves that they have found it to be of little value, and therefore do not sufficiently see how important its proper study would be to students. It is evidently high time that some steps were taken to economise the present waste of time and power, and that we should hear of some good work proceeding from the numerous, and in many cases well-appointed, chemical laboratories connected with our hospitals.

Of late years much attention has been given to the subject of technical or applied chemistry, and it is to be hoped that this movement will be so judiciously carried on that much will be done for perfecting and developing the chemical manufactures in this country; but it appears that there is an idea in the public mind that there are two kinds of chemistry in existence, one suitable for the manufacturer, and the other suitable for the scientific man; and unless this idea can be successfully eradicated, it is to be feared that much of the value of this movement will be lost, and we shall be left in the position of followers instead of leaders; copyists of what others are doing, instead of being originators of new processes and industries.

In the present state of things students who are to be manufacturers are supposed to know enough chemistry when they have acquired a knowledge of ordinary analytical methods, and the result is that we have but very few efficient chemists in our works. On the Continent, however, we find a very different state of things: first of all, in their chemical works they usually have a much larger staff of chemists than we do, and secondly, their chemists are efficient men.

The chemists preferred in Germany are those who have had a thorough training, and taken their degree of Doctor of Philosophy, and shown their power as chemists by conducting original research, and in many cases have been for some time assistants to the professors in their research laboratories. Those from the Polytechnics are not so much valued, except in relation to their knowledge of engineering, mechanics, &c.

What do we see as the result of the employment of high-class chemists in Germany? First, we notice that chemical industries are developing and increasing there more than in any other country; and secondly, that the manufacturers are able to make their products in a very economical manner, and as a consequence supply them at a low price. Men who have studied chemistry sufficiently to do analysis and look after existing processes which are well known are certainly useful in their way; but we want more than this; we want men who have had their minds so trained by carrying on research that they may be imbued with a spirit of investigation, and be able to improve or entirely change processes in use, and to keep up their knowledge of chemical science, so as to be able to grasp the importance of new scientific facts, and make them subservient to the industries they are engaged in.

The chemists from the German Universities, when entering chemical works, naturally have but little knowledge of technical processes. This they have to acquire, but unfortunately they then only are likely to see those operations which are carried on in the particular industry with which they become connected. Those who study in the Polytechnics have a certain advantage in this particular, inasmuch as they can become acquainted with processes carried on in a variety of manufactures; and what is wanted nowadays is something like what would result from a fusion of the work of the Universities and the Polytechnics, *i.e.* scientific training similar to that in the former, with a general knowledge of engineering, mechanics, &c., and the methods adopted in carrying on processes on the large scale, this latter not being confined to one industry only, but also to industries in general, so that great breadth of knowledge may be acquired. With men so trained we might expect to see our chemical industries flourish, and keep at least abreast of those on the Continent.

It is to be hoped that some such standard of training will be undertaken at the Central Institute of the City and Guilds of London. It would be a sad thing to find the munificence of the City Companies resulting only in perpetuating the present kind of imperfectly trained chemists, who are incapable of advancing the chemical industries of this country, so that our manufacturers not unfrequently find it necessary to send to the Continent for more competent men.

In this retrospect of the work which is being carried on in relation to chemistry, it may be thought by some that an undue weight has been given to that which is going on in Germany, and too little to that which is being carried on in this country; but I think if any one will impartially compare one with the other, this will not be found to be the case. Science, however, has no nationality, and as chemists we cannot but be thankful that it is being actively studied, whether abroad or in our own country; but we must feel that it is our duty to do our part, especially when we see, from the work which has been and is being done in this country, that nationally we have the characteristics which qualify us to take a prominent position in work of this nature.

But from the point of view of our national progress we are bound to be active workers in this field of science. There is no doubt we do not hold the position we did as chemical manufacturers, and unless our chemical industries keep pace with chemical discovery fully as well as they do on the Continent, our position must further decline, and moreover, unless we make chemical discoveries ourselves, we must wait until we hear of the discoveries of others, which will mean, in cases where they are susceptible of practical application, that we are placed at a great disadvantage.

The bearing which the progress of chemistry in this country has upon this the oldest Chemical Society in existence is so obvious that it is superfluous to make any observation on the subject, except to express the hope that it will continue to be active, and found doing its part for the advancement of our science, and as a consequence be an important factor in the welfare of our country.

ON THE EVOLUTION OF FORMS OF ORNAMENT[1]

THE statement that modern culture can be understood only through a study of all its stages of development is equally true of its several branches.

Let us assume that decorative art is one of these. It contains in itself, like language and writing, elements of ancient and even of prehistoric forms, but it must, like these other expressions of culture, which are for ever undergoing changes, adapt itself to the new demands which are made upon it, not excepting the very arbitrary ones of fashion; and it is owing to this cause that, sometimes even in the early stages of its development, little or nothing of its original form is recognisable.

Investigations the object of which is to clear up this process of development as far as possible are likely to be of some service: a person is more likely to recognise the beauties in the details of ornamental works of art if he has an acquaintance with the leading styles, and the artist who is freed from the bondage of absolute tradition will be put into a better position to discriminate between accidental and arbitrary and organic and legitimate forms, and will thus have his work in the creation of new ones made more easy for him.

Hence I venture to claim some measure of indulgence in communicating the results of the following somewhat theoretical investigations, as they are not altogether without a practical importance. I must ask the reader to follow me into a modern drawing-room, not into one that will dazzle us with its cold elegance, but into one whose comfort invites us to remain in it.

The simple stucco ceiling presents a central rosette, which passes over by light conventional floral forms into the general pattern of the ceiling. The frieze also, which is made of the same material, presents a similar but somewhat more compact floral pattern as its chief motive. Neither of these, though they belong to an old and never extinct species, has as yet attained the dignity of a special name.

The walls are covered with a paper the ornamentation of which is based upon the designs of the splendid textile fabrics of the Middle Ages, and represents a floral pattern of spirals and climbing plants, and bears evident traces of the influence of Eastern culture. It is called a pomegranate or pine-apple pattern, although in this case neither pomegranates nor pine-apples are recognisable.

Similarly with respect to the pattern of the coverings of the chairs and sofas and of the stove-tiles; these, however, show the influence of Eastern culture more distinctly.

The carpet also, which is not a true Oriental one, fails to rivet the attention, but gives a quiet satisfaction to the eye which, as it were, casually glances over it, by its simple pattern, which is derived from Persian-Indian archetypes (Cashmere pattern, Indian palmettas), and which is ever rhythmically repeating itself (see Fig. 1).

The floral pattern on the dressing-gown of the master of the house, as well as on the light woollen shawl that is thrown round the shoulders of his wife, and even the brightly coloured glass knickknacks on the mantel-piece, manufactured in Silesia after the Indian patterns of the Reuleaux collection, again show the same motive; in the one case, in the more geometrical linear arrangement, in the other, in the more freely entwined spirals.

Now you will perhaps permit me to denominate these three groups of patterns that occur in our new home fabrics as modern patterns. Whether we shall in the next season be able, in the widest sense of the word, to call these patterns modern naturally depends on the ruling fashion of the day, which of course cannot be calculated upon (Fig. 2).

I beg to be allowed to postpone the nearer definition of the forms that occur in the three groups, which, however,

FIG.

on a closer examination all present a good deal that they have in common. Taking them in a general way, they all show a leaf-form inclosing an inflorescence in the form of an ear, or thistle; or at other times a fruit or a fruit-form. In the same way with the stucco ornaments and the wall-paper pattern.

The Cashmere pattern also essentially consists of a leaf with its apex laterally expanded: it incloses an ear-shaped flower-stem, set with small florets, which in exceptional cases protrude beyond the outline of the leaf; the whole is treated rigorously as an absolute flat ornament, and hence its recognition is rendered somewhat more difficult. The blank expansion of the leaf is not quite unrelieved by ornament, but is set off with small points, spots, and blossoms. This will be thought less strange if we reflect on the Eastern representations of animals, in the portrayal of which the flat expanses produced by the muscle-layers are often treated from a purely decorative point of view, which strikes us as an exaggeration of convention.

[1] From a paper by Prof. Jacobsthal in the *Transactions* of the Archæological Society of Berlin.

One cannot go wrong in taking for granted that plant-forms were the archetypes of all these patterns. Now we know that it holds good, as a general principle in the history of civilisation, that the tiller of the ground supplants the shepherd, as the shepherd supplants the hunter: and the like holds also in the history of the branch of art we are discussing,—representations of animals are the first to make their appearance, and they are at this period remarkable for a wonderful sharpness of characterisation. At a later stage man first begins to exhibit a preference for plant-forms as subjects for representation, and above all for such as can in any way be useful or hurtful to him. We, however, meet such plant-forms used in

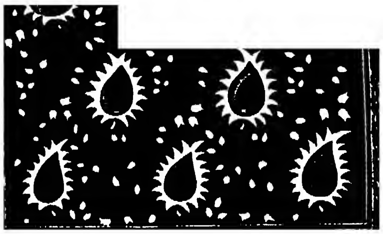

FIG. 2.

ornament in the oldest extant monuments of art in Egypt, side by side with representations of animals; but the previous history of this very developed culture is unknown. In such cases as afford us an opportunity of studying more primitive though not equally ancient stages of culture, as for instance among the Greeks, we find the above dictum confirmed, at any rate in cases where we have to deal with the representation of the indigenous flora as contradistinguished from such representations of plants as were imported from foreign civilisations. In the case that is now to occupy us we have not to go back so very far in the history of the world.

The ornamental representations of plants are of two

FIG. 3.

FIG. 4.

kinds. Where we have to deal with a simple pictorial reproduction of plants as symbols (laurel branches, boughs of olive and fir, and branches of ivy), *i.e.* with a mere characteristic decoration of a technical structure, stress is laid upon the most faithful reproduction of the object possible,—the artist is again and again referred to the study of Nature in order to imitate her. Hence, as a general rule, there is less difficulty in the explanation of these forms, because even the minute details of the natural object now and then offer points that one can fasten upon. It is quite another thing when we have to deal with actual decoration which does not aim at anything further than at employing the structural laws of organisms in order to organise the unwieldy substance, to endow the stone with a higher vitality. These latter forms depart, even at the time when they originate, very considerably from the natural objects. The successors of the originators soon still further modify them by adapting them to particular purposes, combining and fusing them with other forms so as to produce particular individual forms which have each their own history (*e.g.* the Acanthus ornament, which, in its developed form, differs very greatly from the Acanthus plant itself); and in a wider sense we may here enumerate all such forms as have been raised by art to the dignity of perfectly viable beings, *e.g.* griffins, sphinxes, dragons, and angels.

The deciphering and derivation of such forms as these is naturally enough more difficult; in the case of most of

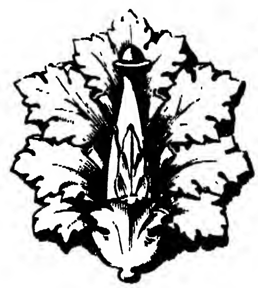

FIG. 5.

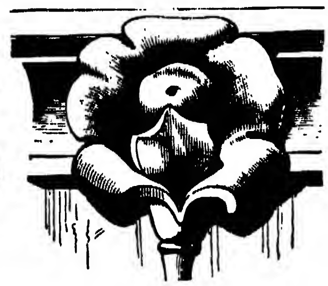

FIG. 6.

them we are not even in possession of the most necessary preliminaries to the investigation, and in the case of others there are very important links missing (*e.g.* for the well-known Greek palmettas). In proportion as the representation of the plant was a secondary object, the travesty has been more and more complete. As in the case of language, where the root is hardly recognisable in the later word, so in decorative art the original form is indistinguishable in the ornament. The migration of races and the early commercial intercourse between distant lands have done much to bring about the fusion of types; but again in contrast to this we find, in the case of extensive tracts of country, notably in the Asiatic continent, a fixity, throughout centuries, of forms that have once been

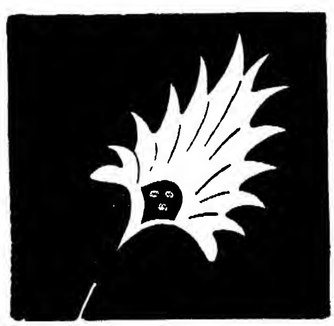

FIG. 7.

FIG. 8.

introduced, which occasions a confusion between ancient and modern works of art, and renders investigations much more difficult. An old French traveller writes:—"J'ai vu dans le trésor d'Ispahan les vêtements de Tamerlan; ils ne diffèrent en rien de ceux d'aujourd'hui." Ethnology, the natural sciences, and last, but not least, the history of technical art are here set face to face with great problems.

In the case in point, the study of the first group of artistic forms that have been elaborated by Western art leads to definite results, because the execution of the forms in stone can be followed on monuments that are relatively not very old, that are dated, and of which the remains are still extant. In order to follow the develop-

ment, I ask your permission to go back at once to the very oldest of the known forms. They come down to us from the golden era of Greek decorative art—from the fourth or fifth century B.C.,—when the older simple styles of architecture were supplanted by styles characterised by a greater richness of structure and more developed ornament. A number of flowers from capitals in Priene, Miletus, Eleusis, Athens (monument of Lysicrates), and Pergamon; also flowers from the calathos of a Greek caryatid in the Villa Albani near Rome, upon many Greek sepulchral wreaths, upon the magnificent gold helmet of a Grecian warrior (in the Museum of St. Petersburg),—these show us the simplest type of the pattern in question, a folded leaf, that has been bulged out, inclosing a knob or a little blossom (see Figs. 3 and 4). This is an example from the Temple of Apollo at Miletus, one that was constructed about ten years ago, for educational purposes. Here is the specimen of the flower of the monument to Lysicrates at Athens, of which the central part consists of a small flower or fruits (Figs. 5 and 6).

The form passes over into Roman art. The larger scale of the buildings, and the pretensions to a greater richness in details, lead to a further splitting up of the leaf into Acanthus-like forms. Instead of a fruit-form a fir-cone appears, or a pine-apple or other fruit in an almost naturalistic form.

In a still larger scale we have the club shaped knob developing into a plant-stem branching off something after the fashion of a candelabra, and the lower part of

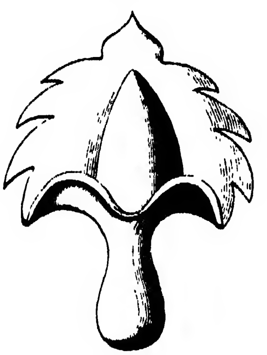

FIG. 9.

the leaf, where it is folded together in a somewhat bell-shaped fashion, becomes in the true sense of the word a campanulum, out of which an absolute vessel-shaped form, as *e.g.* is to be seen in the frieze of the Basilica Ulpia in Rome, becomes developed.

Such remains of pictorial representation as are still extant present us with an equally perfect series of developments. The splendid Græco-Italian vessels, the richly ornamented Apulian vases, show flowers in the spirals of the ornaments, and even in the foreground of the pictorial representations, which correspond exactly to the above-mentioned Greek relief representations. [The lecturer sent round, among other illustrations, a small photograph of a celebrated vase in Naples (representing the funeral rites of Patroclus), in which the flower in question appears in the foreground, and is perhaps also employed as ornament (Figs. 7 and 8).]

The Pompeian paintings and mosaics, and the Roman paintings, of which unfortunately very few specimens have come down to us, show that the further developments of this form were most manifold, and indeed they form in conjunction with the Roman achievements in plastic art the highest point that this form reached in its development, a point that the Renaissance, which followed hard upon it, did not get beyond.

Thus the work of Raphael from the loggias follows in unbroken succession upon the forms from the Thermæ of Titus. It is only afterwards that a freer handling of the traditional pattern arose, characterised by the substitution of, for instance, maple, or whitethorn, for the Acanthus-like forms. Often even the central part falls away completely, or is replaced by overlapping leaves. In the forms of this century we have the same process repeated. Schinkel and Bötticher began with the Greek form, and have put it to various uses; Stüler, Strack, Gropius, and others followed in their wake until the more close resemblance to the forms of the period of the Renaissance in regard to Roman art which characterises the present day was attained (Fig. 9).

Now what plant suggested this almost indispensable form of ornament, which ranks along with the Acanthus and Palmetta, and which has also become so important by a certain fusion with the structural laws of both?

We meet with the organism of the form in the family of the Araceæ or Aroid plants. An enveloping leaf (bract), called the spathe, which is often brilliantly coloured, surrounds the florets, or fruits, that are disposed upon a spadix. Even the older writers—Theophrastus, Dioscorides, Galen, and Pliny—devote a considerable amount of attention to several species of this interesting family,

FIG. 10.

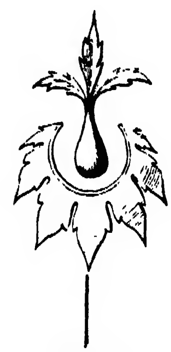

FIG. 11.

especially to the value of their swollen stems as a food-stuff, to their uses in medicine, &c. Some species of Arum were eaten, and even nowadays the value of the swollen stems of some species of the family causes them to be cultivated, as, for instance, in Egypt and India, &c. (the so-called Portland sago, Portland Island arrowroot, is prepared from the swollen stems of *Arum maculatum*). In contrast with the smooth or softly undulating outlines of the spathe of Mediterranean Araceæ, one species stands out in relief, in which the sharply-marked fold of the spathe almost corresponds to the forms of the ornaments which we are discussing. It is *Dracunculus vulgaris*, and derives its name from its stem, which is spotted like a snake. This plant, which is pretty widely distributed in olive-woods and in the river-valleys of the countries bordering on the Mediterranean, was employed to a considerable extent in medicine by the ancients (and is so still nowadays, according to von Heldreich, in Greece). It was, besides, the object of particular regard, because it was said not only to heal snake-bite, but the mere fact of having it about one was supposed to keep away snakes, who were said altogether to avoid the places where it grew. But, apart from this, the striking appear-

ance of this plant, which often grows to an enormous size, would be sufficient to suggest its employment in art. According to measurements of Dr. Julius Schmidt, who is not long since dead, and was the director of the Observatory at Athens, a number of these plants grow in the Valley of Cephisus, and attain a height of as much as two metres, the spathe alone measuring nearly one metre. [The lecturer here exhibited a drawing (natural size) of this species, drawn to the measurements above referred to.]

Dr. Sintenis, the botanist, who last year travelled through Asia Minor and Greece, tells me that he saw beautiful specimens of the plant in many places, *e.g.* in Assos, in the neighbourhood of the Dardanelles, under the cypresses of the Turkish cemeteries.

The inflorescence corresponds almost exactly to the ornament, but the multipartite leaf has also had a particular influence upon its development and upon that of several collateral forms which I cannot now discuss. The shape of the leaf accounts for several as yet unexplained extraordinary forms in the ancient plane-ornament, and in the Renaissance forms that have been thence developed. It first suggested the idea to me of studying the plant attentively after having had the opportunity five years ago of seeing the leaves in the Botanic Gardens at Pisa. It was only afterwards that I succeeded in growing some flowers which fully confirmed the expectations that I had of them (Figs. 10 and 11).

(*To be continued.*)

NOTES

THE International Conference on Education in connection with the International Health Exhibition will be opened on Monday, August 4, at 11 a.m., and will continue throughout the week. The arrangements as yet are not quite complete, but it is announced that the following papers, among others, will be read:—(1) Conditions of Healthy Education:—On the structure, fitting, and equipments of a school, by the Rev. Canon Holland, Canterbury, and Rev. E. F. M. MacCarthy, King Edward's School, Birmingham; on gymnastics and other physical exercises, by Captain Burney, R.N., Royal Hospital School, Greenwich, and H. J. Wilson, J.P., Sheffield; on the right apportionment of time to different subjects of instruction in schools of various classes, by H. W. Eve, University College School, London. (2) Infant Training and Teaching:—What Fröbel did for young children, by Miss Manning; on the relations of the Kindergarten to the various industries of a country, by Fräulein E. Heerwart; on the main work to be accomplished by Kindergartens for the people, and on the methods of training teachers in such institutions, by Madame Schrader, Berlin. (3) Technical Teaching—(*a*) Science, (*b*) Art, (*c*) Handicrafts, (*d*) Agriculture, (*e*) Domestic Economy:—On the methods of teaching the different branches of physical and of natural science, by Henry E. Armstrong, Ph.D., F.R.S.; the teaching of science in public elementary schools, by W. J. Harrison, Birmingham; science teaching in training colleges, by H. A. Reatchlous, Westminster Training College; on the teaching of drawing and colouring as a preparation for designing and decorative work, by John Sparkes, Science and Art Department, A. F. Brophy, Finsbury Technical College, and T. R. Ablett, London School Board; on technical teaching, by Prof. Garnett, University College, Nottingham, and E. M. Dixon, Allen Glen Institute, Glasgow; on technical teaching in Board schools, by J. F. Moss, Sheffield School Board; on manual training schools, by Prof. Woodward, St. Louis, U.S.; (*d*) the teaching of agricultural science in elementary, in intermediate, and higher schools, in evening science classes, in special colleges, and in the Universities, methods of teaching, &c., by the Rev. J. M'Clellan, Royal Agricultural College, Cirencester, J. Wrightson, Wiltshire Agricultural College, and others; on school farms and farm schools, by H. M. Jenkins, Royal Agricultural Society; on methods of teaching cookery in schools, by Miss Fanny Calder, Hon. Sec. Northern Union of Schools of Cookery. (4) Teaching of Music in Schools. (5) Museums, Libraries, and other Subsidiary Aids to Instruction in Connection with Schools:—On school museums, by Dr. Jex Blake, Rugby. (6) Training of Teachers:—By G. B. Davis, Birmingham, and C. Mansford, Wesleyan Training College, Westminster; on some of the differences which exist between the training, position, and duties of elementary teachers in Great Britain and on the Continent, by the Rev. Canon Cromwell, St. Mark's College, Chelsea; Universities and their relations to the training of teachers, by the Rev. R. H. Quick, Sedbergh; professorships and lectureships on education, by Prof. S. Laurie, University of Edinburgh, and Prof. J. M. D. Meiklejohn, St. Andrew's University; on diplomas and certificates and the registration of teachers, by F. Storr; on training colleges in Scotland, by the Rev. J. Morrison, D.D., Glasgow. (7) Inspection and Examination of Schools:—(*a*) By the State, by W. Kennedy, Glasgow; (*b*) by the Universities—on the University local examinations, by the Rev. G. F. Browne, B.D.; on the University extension movement, by Albert J. Grey, M.P., and E. T. Cook; by other public bodies, by the Rev. H. L. Thompson, Iron Acton. (8) Organisation of Elementary Education:—By Sir U. Kay Shuttleworth, Bart., and T. E. Heller; on the English system of elementary education—its growth and present condition, by the Rev. H. F. Roe, Sherborne. (9) Organisation of Intermediate and Higher Education:—On the requirements of a truly national system of higher education and the proper relation of the old Universities to such a system, by R. D. Roberts, Clare College, Cambridge; on the comparative advantages and disadvantages of arranging the course of study in the various school classes on lines of subjects appointed for local University or other general examinations, by the Rev. R. B. Poole, Bedford Modern School; on the advantages and disadvantages of providing for intermediate and higher education by means of a rate, as is done in the case of elementary education, by the Rev. Canon Daniel, and Hon. E. Lyulph Stanley, M.P.; on the organisation of higher education for girls, by Miss Beale, Cheltenham; on the curriculum of a girls' high school, by Mrs. Bryant, B.Sc. (10) Organisation of University Education:—On the proper relation between the teaching and examining bodies in a University, by Sir George Young, Bart.; on scientific teaching in a University, by Prof. Fleeming Jenkin; on the University education of women, by Mrs. H. Sidgwick; on the relation of a University to the colleges, by G. W. Hemming; on the relation of provincial colleges to a University, by E. Johnson, Nottingham; on the duties of the Universities to our Indian Empire, by Prof. Monier Williams.

HER MAJESTY has been pleased to confer a baronetcy upon Mr. Bernhard Samuelson, M.P., and a knighthood upon Prof. Roscoe, in consideration of the services rendered by them in connection with the Technical Education Commission. Sir Bernhard Samuelson well deserves the honour which has been conferred upon him; the services which he has rendered to science and to scientific education both in and out of Parliament, by his insisting for so many years on the importance of science to our national industries, is well known to all our readers.

"A NATURALIST," in a letter to the *Times* of yesterday, again draws attention to the scheme for a Marine Biological Laboratory, showing the practical utility of such an institution by quoting the report of Prof. Brooks on the researches on oysters carried out in the Marine Biological Laboratory founded by the Johns Hopkins University. In a leading article the *Times* very heartily supports the appeal of "A Naturalist" for subscriptions to the Marine Biological Association, an appeal which we hope will be liberally responded to.

IN a communication to us dated Helsingfors, June 23, Prof. Selim Lemström states that, having seen in NATURE that Dr. Sophus Tromholt has entirely failed in producing the artificial aurora borealis in Iceland with one of the "utströmnings" apparatus invented by the Professor, he ascribes this chiefly to the unusually adverse winter, heavy snowfall, and great moisture having frustrated nearly every attempt to produce the aurora in Sodankylä. It is remarkable, the Professor adds, that these circumstances have in no way affected the terrestrial currents, the measurements of which have been highly satisfactory.

THE second number of *La Nuova Scienza* fully maintains the promise of the first, lately noticed in NATURE. The editor, Prof. Enrico Caporali, who contributes most of the papers, continues to deal chiefly with the borderland between physics and metaphysics. His avowed object is to establish a new philosophy based on the reconciliation of idealism and the material order. Hence he revives the speculative doctrines of Campanella, Giordano, Bruno, and Vico, proclaims himself a follower of Kant, in so far as he accepts the Absolute as lying behind the relative, and denounces not only the French materialists but even the modern English Agnostic school. Thought, life, liberty, *la cernita*, that is, "selection" in the Darwinian sense, pervade all nature, the so-called material or inorganic as well as the organic world. Even crystals are "living beings, possessing not the turbulent fiery life of organised species, but a calm and stable life, feeling its harmony and unity, and ever seeking to adapt itself to the environment." And again: "Free selection has done everything in nature. The harmony of beings is the outcome of a long, persistent, unflagging work of fruitful selections inspired by Unity," that is, by the Absolute. In the present number the leading papers are:—"Modern Italian Thought," "The Pythagoric Formula of Cosmic Evolution," and "The German compared with the Italian Anti-clerical Movement."

DR. GLASENAP continues to give in the *Novoye Vremya* further details concerning Russian private observatories. Dr. Endrzeewitsch's observatory at Plonsk is provided with two equatorials, the objectives of which have respectively 162 and 140 mm. diameter; an equatorial telescope, the objective of which is 108 mm.; a transit instrument, three spectroscopes, a Secchi solar eye-piece, and a rich collection of meteorological and physical instruments. Although engaged in the medical profession, Dr. Endrzeewitsch displays a rare energy in the observations of comets, minor planets, Jupiter's satellites, and double stars. His observations of double stars are considered by astronomers as most accurate. General Mayevsky's observatory at Pervino, close to Torjok, is provided with a 6-inch refractor with parallactic motion, and with a transit instrument. Although M. Mayevsky makes observations only during the summer months, his measurements of some double stars and of stars situated in that part of the sky where the moon will be during the next total eclipse of October 4, are worthy of notice. His scientific work is usually described in the Annual Reports of the Pulkowa Observatory.

A DISEASED coffee leaf from Natal has been transmitted to Kew by Prof. Macowan, Director of the Botanic Garden, Cape Town. It has been examined by Mr. H. Marshall Ward, lately employed by the Government in the investigation of the coffee disease in Ceylon, and he finds it attacked with a typical form of the fungus *Hemileia vastatrix*, to which the well-known leaf-disease of that colony is due. This is the farthest westward extension of the disease at present. Eastward it has long maintained a position in Fiji.

PROF. BONNEY asks us to state that the paper which he has promised to the Montreal meeting of the British Association is not, as inadvertently stated in NATURE (p. 218), "On the Archæan Rocks of Canada, &c.," but "On the Archæan Rocks of Britain." Prof. Bonney has not yet visited Canada or examined many of its rocks.

ACCORDING to the *Times* Paris Correspondent, M. Pasteur's experiments with the virus of hydrophobia are going on with unbroken success. He has thus far experimented on 57 dogs, 19 of them mad and 38 bitten by them under uniform conditions. Out of these 38 half had been previously inoculated, the other half not. The latter, without a single exception, died with unmistakable signs of hydrophobia, whereas the 19 others are about and as well as ever. They will be watched for a year by veterinary doctors to see whether the inoculation holds good permanently or only temporarily.

As to chemical *research* in England we print Dr. Perkin's address in another column. As to chemistry as a *trade* we are requested to state that a petition, signed by Prof. Odling, M.A., F.R.S., &c., Professor of Chemistry in the University of Oxford, and others, has been presented to Her Majesty in Council praying for the grant of a charter of incorporation, under the title of the Institute of Chemistry of Great Britain and Ireland. The petition has been referred to a Committee of the Privy Council. The trade seems distinctly to have the best of it!

MR. STANLEY is reported at St. Paul de Loanda to have sailed for England on June 8.

THE city of Rouen has organised in connection with the Concours Regional an exhibition of electricity for the whole of France, and a special exhibition of Algerian products. The number of electrical lamps, regulator and incandescent, is very large, about 400 Swan, some Maxim, 30 Breguet regulators, about 30 Jablokhoff, and 5 or 6 sun lamps. One of the most interesting features is the special exhibit by the Association des Propriétaires of steam-engines of Normandy, who have collected a large number of boilers which have exploded, with labels indicating the causes of explosion.

DR. GULDBERG writes to us with reference to his recent article on the North Cape Whale (vol. xxx. p. 148), that he stated that one of these species of whale was taken at Pampeluna (an inland town); what he meant to have stated was that it was taken at San Sebastian, and brought to Pampeluna. He also finds that Taranto was given as Toronto. Dr. Guldberg informs us that one specimen more of the North Cape Whale has been captured, viz. at Guetaria, not far from San Sebastian, on February 11, 1878; the omission was due to the fact that his article was written during his stay at Liége, where all his books of reference were wanting.

THE additions to the Zoological Society's Gardens during the past week include two Diana Monkeys (*Cercopithecus diana* ♂ ♀) from West Africa, presented by Mr. J. H. Cheetham, F.Z.S.; a Bonnet Monkey (*Macacus sinicus* ♂) from India, presented by Mrs. Norman Yonge; a Razorbill (*Alca torda*), British, presented by Lady Hayter; four Snow Birds (*Junco hyemalis*), an American Coot (*Fulica americana*) from North America, presented by Mr. F. J. Thompson; a Hutchins's Goose (*Bernicla hutchinsi*) from Arctic America, a King Vulture (*Gypagus papa*) from South America, presented by Mr. W. A. Conklin, C.M.Z.S.; a Barn Owl (*Strix flammea*), British, presented by Mr. M. B. Windus; two Angulated Tortoises (*Chersina angulata*), two Areolated Tortoises (*Homopus areolatus*) from South Africa, two Geometric Tortoises (*Testudo geometrica*) from Little Namaqualand, presented by the Rev. G. H. R. Fisk, C.M.Z.S.; two Ceylonese Terrapins (*Clemmys trijuga*) from the Island of Diego, Garcia, presented by Commander the Hon. Foley C. P. Vereker, R.N.; a Pale-headed Tree Boa (*Epicrates angulifer*), an Antillean Snake (*Dromicus antillensis*), two Maculated Snakes (*Ungalia maculata*) from the Island of New Providence, Bahamas, presented by Mrs. Blake; a Tuatera Lizard (*Sphenodon punctatus*) from New Zealand, presented by Surgeon-Major

G. Henderson; a Spotted Cavy (*Cœlogenys paca*), a Blue and Yellow Macaw (*Ara ararauna*) from South America, deposited; a Blue Crested Tanager (*Stephanophorus leucocephalus* ♂) from Brazil, two Cape Doves (*Œna capensis*) from South Africa three Hardwicke's Spur Fowl (*Galloperdix lunulata* ♂ ♀ ♀), two Rufous Spur Fowl (*Galloperdix spadicea*), two Rain Quails (*Coturnix coromandelica*) from India, three Blackish Sternotheres (*Sternothærus subniger*) from West Africa, purchased; a Heloderm (*Heloderma suspectum*) from Mexico, received in exchange; a Burrhel Wild Sheep (*Ovis burrhel* ♂), a Red Deer (*Cervus elaphus*), six Upland Geese (*Bernicla magellanica*), five Long-fronted Gerbilles (*Gerbillus longifrons*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

MINIMA OF ALGOL.—In the calculation of the following Greenwich times of geocentric *minima* of Algol, the later observations of Schmidt have been brought to bear:—

		h.	m.			h.	m.
August	12 ...	14	35	September	24 ..	14	43
	15 ...	11	23		27 ...	11	31
	18 ...	8	12		30 ...	8	20
September	1 ...	16	14	October	14 ...	16	23
	4 ...	13	3		17 ...	13	12
	7 ...	9	51		20 ...	10	0
	12 ...	17	54		23 ..	6	49

It is much to be desired that the observation of this star should be taken up in a systematic manner by one or more observers. We have been indebted to the late indefatigable astronomer at Athens for nearly all the published determinations of *minima* during the last ten years.

THE COMET 1858 III.—Herr Spitaler, of the Observatory at Vienna, who has been searching for some time past for this comet with the 27-inch refractor along the track defined by the calculations of M. Schulhof, remarked on May 26 three small, faint, uncatalogued nebulæ, of which, owing to rapidly-advancing clouds, he was only able to secure the following approximate places:—

		h. m s.		° ′
1.	Right Ascension ...	17 40 50 ...	Declination ...	+ 35 33
2.	,,	17 42 0 ...	,, ...	+ 35 33
3.	,,	17 42 10 ..	,, ...	+ 35 33

A period of almost unexampled bad weather followed, and it was not till June 17 that observations could be repeated: the first of the three nebulæ was then missing, and its disappearance from the position where it had been observed on May 26 was confirmed with the same instrument on the night of June 20. Its place is close upon that given in M. Schulhof's ephemeris if the comet's mean anomaly is assumed to have been 8° 33′ at midnight on May 26.

It is not clear from what elements the positions assigned in the sweeping-ephemeris have been derived. In M. Schulhof's most probable orbit the period of revolution is 6·61 years. If we assume four revolutions to have taken place between 1858 and 1884, we find a period of 6·478 years, and reducing by the factors for $d\mu$ in *Astron. Nach.* No. 2592, in the most probable ellipse, and bringing up the longitudes to May 26, 1884, we have the following constants for the comet's equatorial co-ordinates:—

$$x = r \, . \, [9{\cdot}99985] \, . \, \sin\,(v + 291^\circ\; 27'{\cdot}5)$$
$$y = r \, . \, [9{\cdot}99890] \, . \, \sin\,(v + 201\;\; 33{\cdot}8)$$
$$z = r \, . \, [8{\cdot}87720] \, . \, \sin\,(v + 181\;\; 14{\cdot}6)$$

If the true anomaly, May 26·5 G.M.T., be assumed to be 49° 36′·6, we find that the calculated right ascension agrees with that observed, but the calculated declination is 3° 34′ too small. And M. Schulhof's definitive orbit for 1858 shows a similar discordance in declination, when the computed and observed right ascensions are made to agree. A comparison (made as a check) with the observed longitude and latitude leads to the same inference. It will be of interest to learn upon what elements M. Schulhof has founded his predictions.

If the comet's mean period between 1858 and 1884 were about 6·478 years, it might have approached the planet Jupiter in the middle of September 1880, within 0·97 of the earth's mean distance from the sun, a sufficiently near approach to cause a sensible, though not very important effect upon the elements defining the position of the plane of the orbit.

The intervention of unfavourable weather at Vienna after May 26 was particularly unfortunate, as the comet in the observed position would be receding from both earth and sun, and consequently the intensity of light would be rapidly diminishing, thus rendering a further observation after June 17 almost hopeless. It will remain for M. Schulhof to decide whether the object observed and missed at Vienna was really the comet the return of which he had led astronomers to expect, or another body. Possibly the discordance noticed above may be explained by error in the orbit as printed.

THE PHYSIOLOGICAL BEARING OF ELECTRICITY ON HEALTH[1]

THE reader of the paper commenced by stating that electricity as at present used is at once a source of danger, a possible cause of sickness, and a remedy.

In all these cases it has been insufficiently studied, and continues to be ill understood. This condition of affairs is probably due to the fact that from the great subdivision of modern science, a competent knowledge of physics as well as of physiology is rarely acquired by the same person, whereas, for accurate work it is essential that so powerful an agent should be measured by accepted units. What little has been done by the physiologists is marred by considerable errors as to the force actually in use. Indeed much of it requires total revision in the light of modern discoveries.

1. Dangers to sight were very briefly considered. It was noted that the incandescent and the arc light subjected the eyes to two totally different risks, the former from heat rays at the less refrangible, and the latter from actinic and chemical action at the more refrangible, end of the spectrum. To obtain a sufficient protection in both cases, a pair of eye-protectors, made for the speaker by Mr. Baker of High Holborn, was shown, in which the front glass was blue, and the side "blinker" deep red. The former could be used alone for incandescent lamps, to remove glare, and lessen irritation; while the side glass could be turned down over the blue when powerful arc lights had to be gazed at. If the two tints were well selected and combined by means of the spectroscope, a very handy and simple appliance was obtained, clearly conducive to health. 2. Dangers to life and health were more minutely adverted to. Causes of death may be:—(1) By catalytic action; (2) by thrombosis of the larger vessels; (3) by shock and syncope, due to action on the cardiac nervous system. It was admitted that, considering the enormously increased power of our modern sources of electricity, accidents had been singularly few; and indeed it was abundantly proved that a large steady current, even of considerable magnitude, was comparatively harmless to the human economy. Rapid fluctuations, especially at the starting or breaking of the circuit, were much more dangerous; and still more so if by accident, or by the impregnation of the skin with conducting saline solutions, the resistance of the body was reduced to a minimum. In reviewing the recorded accidents, at the Birmingham Music Hall, in Paris, at Hatfield, and on board the Russian yacht, it was obvious that they were not all to be classified under the third heading given; inasmuch as life in some cases had been prolonged for three-quarters of an hour after the accident. Probably thrombosis in some form would account for them; but more precise information was much needed. Dr. Stone then proceeded to consider certain remedial and physiological points. 1. Several common errors were corrected, especially that of imperfect contact. 2. Any approximate determination of the electrical resistance of the human body to low and high tension currents respectively was described. 3. Use of the telephone and meter-bridge for measuring this resistance demonstrated; and 4. Measurements of E.M.F. of high tension alternating currents by dynanometer and quadrant electrometer were given. Much of this had already appeared in the pages of NATURE on June 14 and September 13, 1883, and on April 3 of the present year. The great need for an electrical testing establishment open to observers at large, like that at Kew, was insisted on, and might well be undertaken by the Society. Lastly, a few suggestions were thrown out as to the therapeutical uses to which electricity, administered, not as now, haphazard, but quantitatively and scientifically, might be put. These were classified as (1) muscular, (2) sensory, (3) neurotic, (4) eliminative, (5) vaso-motorial.

[1] Abstract of a paper by W. H. Stone, M.A., M.B. Oxon, F.R.C.P., Member, at the Conference of the Society of Telegraph Engineers at the Health Exhibition, July 4.

THE MOVEMENTS OF THE EARTH[1]

V.

WE last appealed to those branches of physical science which are connected with the determination of the velocity of light, in order to see whether we could get any help in that direction on a most interesting question, a question which, like another to which attention has been drawn, might have been considered as an open one, unless one had gone beyond the range of ordinary astronomical observation with regard to it. It has now been seen that by investigating the facts connected with the velocity of light, first, that we could determine that velocity by two different methods with a wonderful agreement between them; and secondly, that, by taking the velocity of light and dealing with it in the way we then did, a perfect demonstration was obtained of the fact that the earth revolves in an orbit round the sun. It was further seen that using this velocity of light, and also this fact of the earth's revolution which it enabled us to demonstrate, we were able to say that the distance of the earth from the sun was, roughly speaking, 92½ millions of miles.

We will now go more into detail with regard to the precise form of the earth's orbit, and consider some of the conditions under which the earth's movement in that orbit takes place. In proceeding to do this let us first suppose the orbit of the earth to to be in the form of a circle with the sun in its centre, then it is perfectly clear that the earth will always be at exactly the same distance from the sun, and that consequently the sun as seen from the earth will always appear of the same size; but on the other hand if the earth does not move in a truly circular orbit round the sun, then, unless she moves with great irregularity—and we shall see subsequently that she does not, the only other possible course for her to take is an elliptical one, because if she took an orbit of any other form—that of a parabola or an hyperbola for instance she would not revolve about the sun at all, she would not have a succession of years each of 365¼ days' duration, but one year, a year of infinite length; she would in fact go off at a tangent into infinite space.

Let us then consider what will happen if the earth instead of moving in a circular, travelled in an elliptical, orbit, with the sun in one of its foci, and not in the centre of figure; then it is perfectly clear that the distance of the earth from the sun will vary, that she is nearer the sun at some points of her orbit than at others. So much for supposition. Let us consider the facts. We know that it is the duty of the astronomers at Greenwich to make daily observations, when possible, of the transit of the sun, by means of one of those transit instruments to which reference has been made. Now if the sun, as seen from the earth, had always the same apparent diameter, it is obvious it would always take exactly the same time to cross the central wire of the transit instrument; but when we turn to the record of the observations made at Greenwich we find this:—Take the year 1878. On January 9 in that year the apparent diameter of the sun was 33′ 33″·50 of arc, whereas on July 13 of the same year it was 31′ 30″·24; the apparent diameter was less, so that if these observations are to be depended on—and I know of none better—we were nearer the sun in January 1878 than we were in July. If that be so, then there should be two intermediate points when the diameter of the sun was the same, with an interval of six months between them. This is what was observed on two such dates in this same year, on April 5 an apparent diameter of 31′ 58″·16, and on October 5 an apparent diameter of 32′ 5″·17. In this latter case we have a difference only of 7″·01; in the former case a difference of over 2′, so that the Greenwich observations quite justify the supposition that the earth moves, not in a circle, but in an ellipse; because, the greater the distance of the sun from the earth, the smaller it must appear. While we are on this subject of the ellipticity of the earth's orbit, I am anxious to draw your attention to the two diagrams, so that the matter may be as clear as possible. Let us consider the diagram, Fig. 43. We have drawn there an ellipse, and the earth is assumed to move in the direction of the arrow round the sun placed in one of its foci, S.

Now by the construction of an ellipse we know that S B, which represents the mean distance between the earth and the sun, is exactly the same as the distance A O or P O, which represents what is known as the semi-axis major of the ellipse; further, the eccentricity of any ellipse is defined by the ratio of O S to O A; when the distance O S is very large as compared with O A, then the ellipse is a very flattened one, and the shorter the distance O S as compared with O A the less flattened will be the ellipse and the more nearly will it approach a circle. It will now be clear why the two points are marked A and P, for if S be taken to represent the focus of the ellipse actually occupied by the sun, the point P will represent the place occupied by the earth when it is nearest the sun, which is called by a Greek word, "perihelion," whilst this other point A will mark that point in the orbit of the earth when it is farthest removed from the sun, this being called by another Greek word, "aphelion." This aphelion distance represents the semi-axis major plus the eccentricity, and the perihelion distance of the earth from the sun is obtained by a subtraction of the value of the eccentricity from that of the semi-axis major. These statements are general with regard to ellipses, and in order to make the point quite clear, we have shown them on the very flattened ellipse of Fig. 43, but the true form of the earth's orbit very nearly approaches a circle. If we want to find the greatest distance and the least distance of the earth from the sun at the opposite points of the orbit, we take the best value we can get of the mean distance S B, or O A, which is the same thing, and it is found that the eccentricity comes out about 1½ millions of miles, so that the greatest distance of the earth is less than 94½ millions, whilst its distance at perihelion is a little more than 91¼. So much then for the facts with regard to the varying distances at which the earth is found from the sun at different periods of the year.

The next point is this: if the earth moves in this elliptic path round the sun, does she always move with the same velocity, does she go more quickly at some times than at others, or does she travel always with a steady, constant pace? Now here again the question can easily be answered by an appeal to the

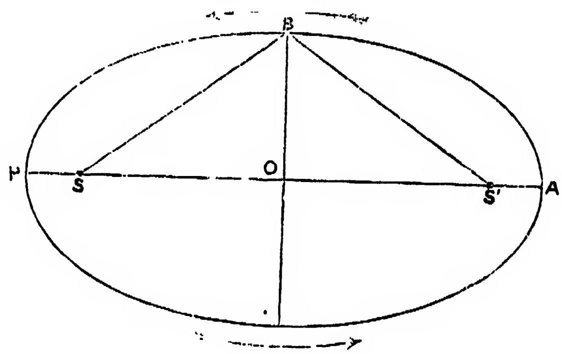

FIG. 43.

useful transit instrument. Our sidereal clock gives us a method, of determining the interval, true to the hundredth part of a second, between one transit of the sun over the central wire of the instrument and another, and so enables us to determine the number of degrees, minutes, seconds, tenths of seconds, and hundredths of seconds of arc passed over by the sun in that time. If the earth, therefore, in her revolution round the sun moves with an equal unchanging motion then it is clear that the number of degrees, minutes, and seconds of arc passed over in any given time will be always the same. Let us again consider the facts according to the Greenwich record. On December 27, 1877, the transit of the sun's centre occurred at 18h. 25m. 44·9s. sidereal time, but on the day before it took place at 18h. 21m. 18·5s. If this second quantity be subtracted from the first, the difference comes out as 4m. 26·4s., that being the amount of arc passed over by the earth in that interval. Now on June 29 of the same year we get 0h. 33m. 51·7s., whereas on the 28th the time was 0h. 29m. 43·3s., a difference of 4m. 8·4s. It is thus obvious that the motion of the earth is not uniform, and that being so, the question arises, Is this want of uniformity constant, or is it irregular? Is there, in short, any law governing it? It will be seen that there is a most perfect law about it; that when the sun looks biggest, that is to say, when we are nearest the sun, the earth moves most quickly, and that when the sun looks smallest from the earth, when the earth is at its greatest distance from the sun, it moves with its least velocity. This fact brings us face to face with a most fundamental law of astronomy—that law which is known as the second law of Kepler. This can be gathered from Fig. 44. Here S represents the sun in one focus of the ellipse

[1] Continued from p. 113.

representing the orbit of the earth, and we have P, P^1, P^2, P^3, P^4, and P^5 representing different positions of the earth at different times of the year, the distance between these points P and P^1, P^2 and P^3, and P^4 and P^5 representing the portions of the orbit passed over by the earth in equal intervals of time. This law is known as the Law of Areas. It states that in equal intervals of time the radius vector or line joining the earth and sun passes over equal areas in its revolution. Thus the area of the triangle S P P^1 is equal to the area of the triangle S P^2 P^3, and is also equal to the area of the triangle S P^4 P^5, and these areas of the orbit are passed over by the radius vector in equal intervals of time. When the earth is nearest to the sun she travels most quickly; when she is at her greatest distance from the sun she

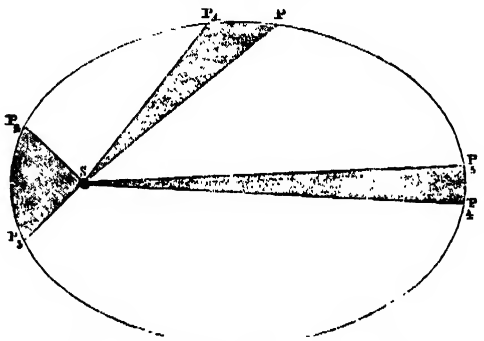

FIG. 44.—Explanation of Kepler's second law.

travels most slowly; and thus she keeps the figures inclosed by the radii vectores always of equal area during equal times. Let us be quite clear on this point: the law is not that the earth moves through equal distances in equal times, but that the areas of the spaces swept over by the radius vector are the same for equal intervals of time.

We come then to this: that the earth moves round the sun; that she moves in an ellipse; that she moves unequally, that is to say, with different velocities at different times, but that these different velocities are bound together by a well-defined and well-recognised law.

Now comes another question connected with this movement of the earth round the sun. When the movement of the earth on its axis was being discussed, it was pointed out that observations made by the transit instrument gave ample evidence that the movement was a perfectly equable one, and of such a nature that the axis of movement remained always practically parallel to itself. Attention must now again be turned to this axis of rotation. Let us take the earth in any part of its orbit, then the question is this: Is the plane of the earth's motion round the sun, or, as it must now be called, the plane of the ecliptic, identical with the plane of the earth's motion of rotation? That is to say, if the earth were half immersed in an ocean of infinite extent, whilst it was performing its orbital motion, would its axis of rotation be at right angles to the surface of the ocean in which it swam. Suppose we had a globe to represent the earth, and on it a model of a transit instrument were placed in the direction it is pointed at Greenwich when the sun is being observed. Then if the axis of the earth were really vertical the instrument would always be at right angles to it, or practically so, for sun observations. Further, if the model were turned round to represent one rotation of the earth, then if the axis on which it turned were really perpendicular, the sun's declination would remain unchanged, and its polar distance would always be 90°. Now let us refer to the Greenwich observations of the north polar distance of the sun.

On March	16	N.P.D. was	91°·34
,,	22	,,	89·12
June	22	,,	66

That is to say, the observers at Greenwich in going from March to June had to alter the inclination of their instrument, in consequence of this variation in the N.P.D. of the sun, to the extent of the difference between 90° and 66°. On September 21 of the same year the N.P.D. was 90°, but on December 17 instead of being 90°, or 66°, it was 113°·24. How can these facts be explained? Suppose we had a lighted lantern to represent the sun, and round it four globes were placed with their axes vertical to represent the earth in four different positions in its orbit. It will be obvious that if we bring the light of the lamp in succession upon the four globes with the axes in each thus vertical, then the zenith distance of the sun, represented by the lamp, would be the same in each case. In this position of the globes we get the boundary of light and darkness at the poles, and the line joining the centres of earth and sun

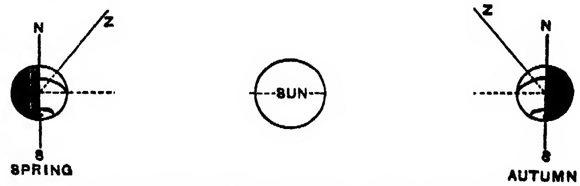

FIG. 45.—Diagram showing the equality of the sun's zenith distance at the two equinoxes. N, north pole of the earth; S, south pole; Z, zenith of Greenwich.

will give us the zenith distance of the latter. Now assume that the axis of the earth is not vertical but is inclined 23½° to the plane of the ecliptic. In that case its spin of course would not be at right angles to this plane. If the four globes were then illuminated in succession, it would be found that the presentation of Greenwich to the sun would be vastly different at the four

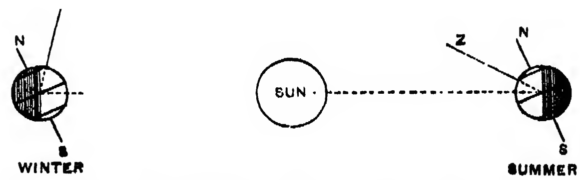

FIG. 46.—Diagram showing the variation of the sun's zenith distance from solstice to solstice. N, north pole of the earth; S, south pole; Z, zenith of Greenwich.

different positions. In the first, if it were placed in the proper part of the orbit, we should get Greenwich, not turned fully to the sun, but still well in his rays. In the second one we should find the vertical at Greenwich pointing very much more to the sun than before, when the axis was vertical. In the third globe the conditions would be about the same as in the first, while in

FIG. 47.—The earth, as seen from the sun at the summer solstice (noon at London).

the fourth the line which points towards the zenith at Greenwich, instead of being turned almost directly to the sun, would be turned most away from it. This fourth position is that in which the zenith distance, and therefore the N.P.D., was greatest, *i.e.* when it was 113°. The second represents the position of the earth when it was the least possible, whilst the first and third positions would

occur when the N.P.D. of the sun was neither great nor small, but midway between the two extremes. These facts will be made clearer by the accompanying woodcuts, in which the globes are shown in four different positions. Fig. 45 represents cases 1 and 3, and Fig. 46 cases 2 and 4. In Figs. 47 and 48 these facts are shown in different ways: Fig. 47 represents the aspect of the earth as seen from the sun at the summer solstice, when it will be seen that England is seen to lie near to the centre of the hemisphere; while in Fig. 48, representing the conditions at the winter solstice, England is so near the edge that it cannot be properly represented. This experiment then will enable us to go further, and to say that the plane of the earth's equator, and therefore of the earth's spin, is not parallel to the plane of the ecliptic, but is inclined to it at an angle represented by the difference between 90° and 66°, or 90° and 113°; that is to say, the angle between these two planes, that of the earth's rotation and that of its revolution, is something like 23°.

In the non-coincidence of these two planes we have one of the most fundamental points in astronomy, for the reason that what Greenwich is to earth measurement the point of intersection of these two planes is to heaven measurement. The result of this inclination of these two planes is that at one particular point in its course round the sun the equatorial plane of the earth seems to plunge below the plane of the ecliptic, whilst at another and an opposite point it seems to come up from below that plane.

These two points are known as the nodes of the orbit, the

FIG. 48.—The earth, as seen from the sun at the winter solstice (noon at London).
